Among older infants and children, bacterial presence is commonly established in the lower respiratory tract as a result of oropharyngeal overgrowth of environmentally acquired pathogens and subsequent introduction of these secretions into the lower airways. Children with aspiration syndromes, immunodeficiencies, and malformations of the respiratory tract are at increased risk of lower respiratory bacterial infection.¹⁰⁰ Bacterial pathogens remain an important cause of potentially lethal pediatric pneumonias in the developing world, and they are the most important cause of severe pneumonia in Europe and North America, especially when complicated by parenchymal necrosis and/or parapneumonic effusion.⁸⁴ It is challenging to establish a causal role for specific bacteria when these agents are normally found in the

upper airway secretions, the specimen that is most commonly sampled for microbiologic diagnosis in children. The best data regarding the etiology of community acquired pneumonia come from lung puncture studies revealing that *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *S. aureus* are among the most important causes.⁸⁴ Since the introduction of a conjugate vaccine against *H. influenzae* type B (Hib) in 1988, the incidence of invasive disease in infants and young children attributed to this organism has declined by 99%.⁸⁵ Other serotypes of the organism, including nonencapsulated strains, are also capable of causing pneumonia in children.⁸⁵

A comprehensive review of necrotizing pneumonia cases occurring in predominantly immunocompetent children admitted to Boston Children's Hospital between 1990 and 2005 indicates that parenchymal necrosis appears to be an increasingly common complication of pediatric bacterial pneumonia.¹⁰² In this series, *S. pneumoniae* was the predominant inciting organism, accounting for 22% of cases. Since 2002, many more organisms, including methicillin-sensitive *S. aureus*, methicillin-resistant *S. aureus*, *Fusobacterium* species, *Pseudomonas* species, and other *Streptococcus* species, have emerged as important causes of necrotizing pneumonia, as well. Despite the short-term morbidity in these children, conservative management (consisting mainly of antibiotics and chest drainage) appeared sufficient to produce resolution of clinical symptoms within 2 months of hospital discharge, and marked improvement of imaging findings within 6 months.

Recent studies on the epidemiology of pediatric pneumonia complicated by parapneumonic effusions indicate that the incidence of empyema appears to have risen during the 1990s.¹⁰³⁻¹⁰⁵ During that period *S. pneumoniae* was isolated most commonly from patients with empyema, followed by *S. pyogenes* and *S. aureus*.^{104,105} As in the case of necrotizing pneumonia, temporal trends in the epidemiology of pediatric empyema in the United States show a shift in causative organisms after 2000, when the heptavalent pneumococcal conjugate vaccine (PCV) was licensed for widespread use. Since 2000, *S. aureus* has overtaken *S. pneumoniae* as the most common bacterial pathogen isolated from children with empyema, and the *S. aureus* isolates are often methicillin resistant.¹⁰³ In addition, nonvaccine serotypes (particularly serotypes 1, 3, and 19A) predominate among causes of pneumococcal empyema in the post-PCV era.^{104,106} The overall impact of widespread vaccination with PCV on the incidence of pediatric empyema across the United States is less clear. In Utah, where pneumococcal serotype 1 has always been prevalent, the incidence of pediatric empyema is still rising, while data from Texas Children's Hospital show a decrease in the incidence of empyema since the vaccine became available.^{103,104}

Therapy

In the clinical setting, one is often faced with having to select empiric antimicrobial therapy before arriving at a definitive viral or bacterial diagnosis. The presence of a focal alveolar process on chest radiographs, especially if accompanied by significant parapneumonic effusions, evidence of parenchymal necrosis, and/or abnormal peripheral blood counts and C-reactive protein all add considerably to the predictive value for the presence of bacterial disease.⁸⁴ Before demonstrating evidence of localized infection, neonates and young infants may demonstrate nonspecific but potentially ominous signs of lethargy, hypothermia, and apnea. Infants less than 3 months of age should be treated with a broad spectrum combination of antibiotics such as ampicillin and gentamicin, and consideration should be given to adding a third-generation cephalosporin in severe cases.⁸⁴ Investigation and empiric coverage for infection with *B. pertussis* should also be considered in infants with severe respiratory disease that features profound peripheral lymphocytosis, paroxysmal cough, and/or apnea.

For critically ill children with community-acquired bacterial pneumonia, reasonable coverage may be assured with a third-generation cephalosporin,^{84,100} although some centers advocate the use of clindamycin as a second empiric agent. A macrolide antibiotic can be added in cases where infection with atypical agents such as *Mycoplasma*

pneumoniae and *Chlamydia pneumoniae* is possible, particularly in patients with sickle cell disease.^{84,107} Although emerging resistance to penicillins in *S. pneumoniae* is widely recognized, high doses of cephalosporins are still appropriate in the majority of penicillin-nonsusceptible strains, as long as concurrent meningitis is not suspected, but the addition of vancomycin may be warranted in some cases.^{84,108} If infection with *S. aureus* is possible, an antistaphylococcal penicillin such as oxacillin should be added, unless local resistance patterns warrant the use of vancomycin.⁸⁴ In patients at risk for aspiration pneumonia and in immunocompromised children, special consideration should be given to administration of two antibiotics effective against gram-negative organisms (such as *Pseudomonas*) and to optimizing coverage for anaerobic organisms.

Management of pleural effusions is another important consideration in the care of patients with bacterial pneumonia. Although drainage of parapneumonic effusions is indicated under certain circumstances, satisfactory recovery may occur in many cases without intervention.¹⁰⁹ An evidence-based clinical practice guideline was developed for the medical and surgical treatment of parapneumonic effusions in adults.¹¹⁰ The panel issued management suggestions according to the underlying risk of poor clinical outcome based on effusion size and loculation, as well as chemical and microbiological analysis of the pleural fluid.¹¹⁰ Pleural fluid drainage was recommended for large effusions occupying less than 50% of the hemithorax, whether or not loculation or pleural thickening is present. Drainage was also recommended for purulent effusions, those with positive culture or Gram stain, or those with pH less than 7.20 as measured by a blood gas analyzer.¹¹⁰ In situations where drainage is indicated, more complex or invasive options such as thorascopic or "open" procedures are likely to be necessary for sufficient control of the effusion.¹¹⁰ The consensus panel's recommendations are based primarily on case series, historic controls, and expert opinion.¹¹⁰

Currently, the literature on parapneumonic effusions in children also does not provide robust evidence on which to base clinical interventions. The effect of image-guided needle aspiration versus percutaneous pigtail catheter drainage was examined in a 5-year retrospective study of pediatric parapneumonic effusions.¹¹¹ When comparing outcomes in the two groups, the authors found no difference in the length of stay but did report a significant decrease in the need for a second intervention in patients who received a chest drain.¹¹¹ Other independent predictors for a second intervention in their study population included loculation of pleural fluid and a pH of less than 7.2. A combination of low glucose and low pH in the pleural fluid specimen was especially predictive of the need for reintervention.¹¹¹ The decision to perform thoracostomy drainage in pediatric patients with parapneumonic effusion may depend on the clinical context in which it occurs. In cases where significant pleural fluid organization has taken place, some favor the administration of intrapleural thrombolytics to facilitate evacuation of fluid through the chest drain.¹¹² Studies assessing the efficacy of this practice have produced conflicting results. In one uncontrolled case series, 54 of 58 children (93%) with pneumonia complicated by empyema who received intrapleural tissue plasminogen activator (tPA) did not require additional surgical drainage.¹¹³ However, an RCT that enrolled 454 adults with empyema showed no outcome benefit attributable to the administration of intrapleural thrombolytics, compared to chest drainage and routine supportive care alone.¹¹⁴ In recent years, video-assisted thoracoscopic surgery (VATS) has gained popularity as a way to facilitate chest drainage through inspection of the pleural space, disruption of adhesions, and placement of chest drains in strategic locations.¹¹² To date, at least two prospective pediatric trials have failed to identify an outcome advantage attributable to VATS when compared to thrombolytic-enhanced chest drainage and routine supportive therapy for empyema.^{115,116}

In summary, it is certainly important to drain large parapneumonic effusions when they are suspected of causing hemodynamic instability in critically ill children. Pleural drainage may also be useful to relieve respiratory embarrassment that may contribute to respiratory failure or ongoing ventilator dependence. The best opportunity to achieve

sufficient drainage is probably in the first 48 to 72 hours, before organization of the effusion begins to take place. An RCT is necessary to resolve the issue of which pediatric patients with parapneumonic effusions would benefit from aggressive pleural drainage.

Acute Lung Injury and Acute Respiratory Distress Syndrome

What was once known as the *adult respiratory distress syndrome* is now called the *acute respiratory distress syndrome* (ARDS) in an effort to acknowledge its prevalence in the pediatric population. ARDS describes a diverse group of conditions for which the final common pathway involves the onset of permeability edema, parenchymal opacification, and significant oxygenation impairment. The syndrome can arise as a consequence of primary pulmonary disease or as a feature of systemic pathophysiology that is nonpulmonary in origin. Although ARDS had been described in adults for many years, consensus criteria for the diagnosis of the syndrome did not enter the scientific literature until 1994.¹¹⁷ The American European Consensus Conference's (AECC) establishment of highly sensitive diagnostic criteria for ARDS and acute lung injury (ALI), the less severe form of the disease, facilitated the conduct of large-scale RCTs that have added considerably to our understanding of the epidemiology, pathophysiology, and outcomes of both conditions. Published incidence estimates for ALI/ARDS vary and are best interpreted in the context of study design, case ascertainment methods, population demographics, and mechanical ventilation practices that were used at the time patients were identified as meeting criteria for either condition. The available data suggest that there are striking differences in the incidence of ALI and ARDS in children as compared to adults (Table 77-3).

As defined by AECC diagnostic criteria, ARDS is estimated to account for 1% to 4% of all PICU admissions, or ~10% of all children

requiring mechanical ventilatory support.^{118,119} Pneumonia, which was responsible for 35% of cases in a recent epidemiologic study, appears to have overtaken sepsis as the most common cause of pediatric ARDS.¹¹⁸ Reported mortality rates for children with ARDS have fluctuated over time, depending on the criteria used to identify cases, the presence of important comorbidities such as immunocompromise and nonpulmonary organ failures among patients in the cohort, and the quality and consistency of supportive care provided in the ICU. Data from contemporary epidemiologic investigations and the control groups of multicenter clinical trials conducted during the past decade indicate that mortality in the pediatric ALI/ARDS population ranges between 8% in both arms of a prone positioning trial¹²⁰ in which the investigators protocolized nearly every conceivable aspect of supportive therapy to 36% in the control arm of an RCT of exogenous surfactant administration.¹²¹ Among immunocompromised children, mortality may be as high as 60%.¹²¹⁻¹²⁴ As is the case in the adult literature, the lowest mortality rates for ALI/ARDS are reported in trials that evaluate the efficacy of a particular therapy while introducing it in the context of contemporary, evidence-based supportive care protocols.^{120,125,126}

The past 2 decades have seen the completion of many multicenter trials designed to investigate the effects of various adjuvant therapies in pediatric and adult ALI and ARDS (Table 77-4). So far, prone positioning¹²⁷ and tidal volume reduction during mechanical ventilation¹²⁸ stand as the only interventions proven to offer a significant mortality benefit to patients with ALI and ARDS. Having reached a point at which clinical trials are consistently unable to demonstrate outcome benefits for well-rationalized candidate therapies for ARDS, we now enter a new era obligating further refinement of diagnostic criteria, with an eye toward identifying relevant subgroups of ARDS patients who may stand to benefit from treatments whose merits may not be apparent in more unselected populations. The ARDS Definition Task Force and the Pediatric Acute Lung Injury Consensus Conference (PALICC) Group have each proposed updated diagnostic criteria for adult and pediatric patients that make an effort to address various aspects of the AECC consensus criteria that clinicians now recognize as potentially problematic.^{129,130} First, $\text{PaO}_2/\text{FiO}_2$ can be manipulated by altering ventilator settings. Second, acute lung injury can often coexist with hydrostatic pulmonary edema. Third, there is an increasing trend toward monitoring oxygenation in mechanically ventilated pediatric patients without indwelling arterial access. Finally, there exists considerable variability among radiologists in interpreting chest radiographs.¹³¹ Each group proposed eliminating the term *acute lung injury* in favor of simply classifying the degree of oxygenation impairment in ARDS patients as “mild,” “moderate,” or “severe”—in accordance with data indicating that mortality risk is concordant with the severity of oxygenation impairment in each category.¹²⁹ The PALICC group also defined a cohort of patients “at risk for” pediatric ARDS, a move intended to facilitate future research on preventative strategies.¹³⁰ It is evident from their final form (Table 77-5) that both new definitions foreclose the possibility that ARDS can be diagnosed in patients not requiring mechanical ventilation—a change that seems appropriate in light of the multiple lines of evidence suggesting a major role for mechanical ventilation in the pathogenesis of this disease.

Mechanical Ventilation

Mechanical ventilatory support of patients with ALI/ARDS is often necessary to provide adequate oxygenation. In relatively stable patients, noninvasive ventilation may be effective when instituted early in the disease process. This method has been used successfully in the management of acute hypoxic respiratory failure in a heterogeneous population of adult patients¹³² and in a more selected population of immunocompromised adult patients.¹³³ Each of these RCTs showed that early use of noninvasive ventilation decreased the need for intubation and reduced the risk of death in the ICU and in the hospital. Data on the use of noninvasive positive pressure ventilation in pediatric patients are limited, but several case series report success with the

TABLE 77-3

American-European Consensus Criteria for Acute Lung Injury (ALI) and the Acute Respiratory Distress Syndrome (ARDS)

| | ALI | ARDS |
|----------------------------|---|---|
| TIMING | ACUTE ONSET | ACUTE ONSET |
| Chest radiography | Bilateral pulmonary infiltrates | Bilateral pulmonary infiltrates |
| Edema | Pulmonary artery occlusion pressure ≤ 18 mm Hg or no clinical evidence of left atrial hypertension | Pulmonary artery occlusion pressure ≤ 18 mm Hg or no clinical evidence of left atrial hypertension |
| Oxygenation impairment | $\text{PaO}_2/\text{FiO}_2$ ratio $\leq 300^*$ | $\text{PaO}_2/\text{FiO}_2$ ratio $\leq 200^*$ |
| ESTIMATED INCIDENCE | | |
| Adults | 17.9-78.9 ^a cases per 100,000/year ²²³⁻²²⁵ | 14-58.7 ^b cases per 100,000/year ^{224,225} |
| Children | 2.95-12.8 ^c cases per 100,000 children/year ²²⁶⁻²²⁸ | 2.2-9.5 ^c cases per 100,000 children/year ^{226,227,229,230} |

*At altitudes exceeding 1000 m, $\text{PaO}_2/\text{FiO}_2$ should be adjusted for local barometric pressure ($\text{PaO}_2/\text{FiO}_2 \times (\text{barometric pressure}/760)$). ^aIncidence of ALI/ARDS in adults depends on age. Among adolescents, the incidence has been reported as low as 16/100,000.²²⁵ ^bThe incidence of ARDS among adults may be decreasing to as low as 38.9/100,000.²³¹ ^cHigh estimate for pediatric ALI and ARDS incidence comes from a cohort assembled between 1999 and 2000 who were ventilated with a mean (\pm SD) Vt of 9.3 ± 1.5 cc/kg.²²⁷ The most recent large, population-based cohort including children receiving lung-protective mechanical ventilation suggests an ARDS incidence of 3.9/100,000 children per year.²²⁹

Baltimore: Lippincott Williams and Wilkins, in press.

TABLE 77-5 The Acute Respiratory Distress Syndrome: Revised Diagnostic Criteria

| BERLIN DEFINITION | | PEDIATRIC ARDS (PARDS) DEFINITION [§] | |
|-----------------------------|---|---|--|
| Timing | Onset within 1 week of a known clinical trigger or new/worsening respiratory symptoms | Onset within 1 week of a known clinical trigger | |
| Chest imaging (x-ray or CT) | Bilateral opacities not fully explained by effusion, regional atelectasis, or nodules | New radiographic infiltrates consistent with acute pulmonary parenchymal disease | |
| Origin of edema | Respiratory failure not fully explained by cardiac failure or fluid overload ^{**} | Respiratory failure not fully explained by cardiac failure or fluid overload [*] | |
| Oxygenation impairment | | Noninvasive ventilation ^{††} | Invasive mechanical ventilation [‡] |
| Mild ARDS [*] | 200 < PaO ₂ /FiO ₂ ≤ 300 with PEEP or CPAP ≥ 5 cm H ₂ O [†] | PaO ₂ /FiO ₂ ≤ 300 SpO ₂ /FiO ₂ ≤ 264 | 4 ≤ OI < 8 OR 5 ≤ OSI < 7.5 8 ≤ OI < 16 OR 7.5 ≤ OSI < 12.3 OI ≥ 16 OR OSI ≥ 12.3 |
| Moderate ARDS [*] | 100 < PaO ₂ /FiO ₂ ≤ 200 with PEEP ≥ 5 cm H ₂ O | | |
| Severe ARDS [*] | PaO ₂ /FiO ₂ ≤ 100 with PEEP ≥ 5 cm H ₂ O | | |

^{*}At altitudes exceeding 1000 m, PaO₂/FiO₂ should be adjusted for local barometric pressure (PaO₂/FiO₂) × (barometric pressure/760).

^{**}Objective assessment such as echocardiography is needed to exclude hydrostatic edema in the absence of specific risk factor(s).

[†]Noninvasive positive pressure ventilation may be provided in mild ARDS.

^{††}Full face mask bilevel ventilation or CPAP ≥ 5 cm H₂O. No severity stratification for pARDS diagnosed in patients on noninvasive ventilatory support. If SpO₂/FiO₂ is used to quantify the degree of oxygenation impairment, FiO₂ should be titrated to keep SpO₂ 88%-97%.

[‡]Diagnostic criteria exclude infants and children with perinatally related lung disease.

[§]Oxygenation index (OI) = 100 × (FiO₂ × mean airway pressure)/PaO₂; oxygen saturation index (OSI) = 100 × (FiO₂ × mean airway pressure)/SpO₂. If OSI is used to quantify the degree of oxygenation impairment, FiO₂ should be titrated to keep SpO₂ 88%-97%. Children with cyanotic congenital heart disease and those with chronic lung disease and dependence on invasive mechanical ventilation should not be stratified into pARDS severity groups.

Adapted from Ranieri M, et al., JAMA 2012;307:2526-2533 and Pediatric Acute Respiratory Distress Syndrome: Consensus Recommendations from the Pediatric Acute Lung Injury Consensus Conference. *Pediatr Crit Care Med* 2015 (16) DOI 10.1097.

application of this technique in children with alveolar disease.^{134,135} In one study, noninvasive bilevel positive airway pressure was used to support pediatric patients with pneumonia, acute chest syndrome and sickle-cell disease, underlying chronic hypoventilation syndromes, and postoperative hypoventilation with atelectasis.¹³⁴ The authors reported favorable changes in respiratory rate, heart rate, and oxygenation among all patients receiving noninvasive support, and 91% of respiratory failure episodes in their study were reversed without the need for intubation.¹³⁴

When noninvasive techniques are not appropriate or have failed, tracheal intubation is warranted. It is established that mechanical ventilation can have a profound influence on the course of disease and on the overall clinical outcome.^{77,136-139} Chief among these is the landmark multicenter study conducted by the ARDS Network (ARDSnet) investigators, which established that ALI/ARDS patients randomized to receive tidal volumes of 6 cc/kg ideal body weight had a mortality reduction of 22% relative to those who received ventilation using "traditional" tidal volumes of 12 cc/kg ideal body weight.⁷⁷ This trial also demonstrated a greater reduction in plasma levels of the pro-inflammatory cytokine interleukin-6 among those patients randomized to receive lower tidal volumes, suggesting that reducing the magnitude of phasic stretch during mechanical ventilation can actually attenuate the systemic inflammatory response. Over the past decade, much attention has been given to the provision of "lung-protective" mechanical ventilation in patients with ALI/ARDS. Lung-protective ventilation involves (1) the preservation of end-expiratory lung volume by judicious use of PEEP in order to minimize atelectrauma; (2) the minimization of cyclic stretch; and (3) the avoidance of parenchymal overdistention at end inspiration by limiting tidal volume and transpulmonary pressure (Fig. 77-6).^{77,136-139} Consensus recommendations recently issued by the PALICC group call for limiting tidal volumes to 3 to 6 mL/kg predicted body weight for infants and children with the most impaired pulmonary compliance and maintaining pH between 7.15 and 7.30. More "physiologic" tidal volumes (5 to 8 mL/kg predicted body weight) are allowed for those with more favorable compliance, provided the inspiratory plateau pressure remains 28 to 32 cm H₂O or less.¹³⁰

**FIGURE 77-6 ■ Pressure-volume relationships in acute lung injury.**

The lower curve shows the pressure-volume relationships during inspiration. The upper curve shows the pressure-volume relationships during exhalation. Note that during exhalation (as compared to inspiration), larger lung volumes can be maintained at lower transpulmonary pressures. Combining moderate to high end-expiratory pressures with small tidal volumes minimizes the potential for cyclic derecruitment (lower left) and overdistention (upper right). (From Froese AB. High-frequency oscillatory ventilation for adult respiratory distress syndrome: let's get it right this time! *Crit Care Med* 1997;25:906-908.)

When oxygenation failure is refractory to noninjurious strategies of conventional ventilation, HFOV is an alternative modality with a long history of use in the pediatric population. During HFOV, lung recruitment is maintained by application of a relatively high mean airway pressure with superimposed pressure oscillations at a frequency

of 3 to 15 Hz.¹³⁹ Because maximal recruitment is maintained throughout the respiratory cycle and ventilation is achieved using very small phasic changes in pressure and volume, this technique allows the lung to be ventilated above the critical opening pressure of injured lung units while avoiding end-inspiratory overdistention of more compliant lung units (see Fig. 77-3).¹⁴⁰⁻¹⁴² This “open lung” strategy of mechanical ventilation can capitalize on pulmonary hysteresis in order to achieve satisfactory gas exchange at lower alveolar pressures (see Fig. 77-3). In 1994, a prospective multicenter, randomized clinical study compared HFOV and conventional mechanical ventilation in pediatric patients with diffuse alveolar disease or air leak syndromes.¹⁴³ Patients in the HFOV arm showed rapid and sustained improvements in oxygenation without suffering adverse effects on ventilation.¹⁴³ Ultimately these patients showed a decreased incidence of ventilator-associated lung injury as evidenced by a decreased need for supplemental oxygen at 30 days and demonstrated improved outcomes compared to their cohorts in the conventional arm, particularly when HFOV was instituted within 72 hours of intubation.¹⁴³ The oxygenation index (OI), defined as $(\text{mean airway pressure} \times \text{FiO}_2 \times 100) / \text{PaO}_2$, used often in the pediatric literature to quantify oxygenation failure, was shown to discriminate between survivors and nonsurvivors in the first 72 hours of therapy.¹⁴³ Furthermore, the time at which changes in the OI were found to occur seemed to influence the likelihood of survival: an OI equal to or more than 42 at 24 hours predicted mortality with an odds ratio of 20.8, a sensitivity of 62%, and a specificity of 93%.¹⁴³ In the time since this study was published, other investigators have helped to establish that the OI seems to be a time-sensitive predictor of survival in patients with hypoxic respiratory failure and that OI trends can be used to facilitate decisions about the need for extracorporeal support in patients with acute hypoxic respiratory failure.¹²²

There has been a recent tempering of enthusiasm for offering HFOV to adult ARDS patients, after two recent large-scale multicenter clinical trials involving a total of 1343 patients were unable to demonstrate a mortality benefit from HFOV in this population.^{144,145} The Oscillation for Acute Respiratory Distress Syndrome Treated Early (“OSCILLATE”) trial¹⁴⁴ enrolled patients within 72 hours of meeting eligibility criteria. This trial used a “maximally protective” high mean airway pressure HFOV strategy and was terminated well before reaching its goal of recruiting 1200 patients, after a planned interim analysis revealed that the HFOV group had an in-hospital mortality rate of 47% compared to 35% for the conventional ventilation group (RR for mortality with HFOV 1.33; 95% CI, 1.09-1.64; $P = 0.005$). Nearly half of the patients in each study arm had a diagnosis of sepsis. As compared to their counterparts in the control group, a significantly higher proportion of patients randomized to the HFOV group required vasoactive medications (91% vs. 84%; $P = 0.01$), neuromuscular blocking agents (83% vs. 68%; $P < 0.001$), and higher median doses of midazolam (199 mg/day [IQR 100-382] vs. 141 mg/day [IQR 68-240]; $P < 0.001$). Whether or not these data provide “definitive” information regarding the relative benefits and potential harms of HFOV, they could be pointing toward a few important insights. First, early institution of a high mean airway pressure HFOV strategy may not be advisable for patients whose underlying diagnosis (e.g., sepsis) and perceived supportive care requirements (e.g., deep sedation and neuromuscular blockade) may render them vulnerable to problematic levels of hemodynamic instability. Second, the study’s use of an HFOV management protocol that called for an initial mean airway pressure setting of 30 cm H₂O with incremental adjustment according to the FiO₂ may deserve consideration. In septic patients who are early in their clinical course, initiating HFOV at a mean airway pressure of 30 cm H₂O and adjusting upward from that point could exacerbate hemodynamic instability by creating conditions in which alveolar pressure exceeds pulmonary vascular pressure throughout the respiratory cycle. This would set the stage for increased right ventricular afterload and impaired left ventricular compliance. Ultimately, HFOV may be a technique better suited for patients with diffuse alveolar disease that is coupled with increased chest wall compliance—conditions that commonly coexist in infants and young children with ALI/ARDS.

DISEASES OF THE INTERSTITIUM

The interstitial lung diseases (ILD) in children are a diverse group of rare conditions that involve alteration of the alveolar wall, infiltration and fibrosis of the pulmonary interstitium, and loss of functional alveolar-capillary units.¹⁴⁶ The major clinical findings include abnormal gas exchange, tachypnea, and crackles, as well as the potential for both restrictive and obstructive pulmonary physiology.¹⁴⁷ In children, as in adults, the morbidity and mortality of ILD can be high,^{148,149} but the frequency distribution and prognostic implications of specific conditions appear to be very different in the two populations. Our collective sense of the prevalence of specific ILD subtypes in the pediatric population has shifted in recent years, following the publication of an international consensus statement on pediatric ILD classification (Box 77-2) and a follow-up report issued by the European Respiratory Society’s task force on chronic ILD in immunocompetent children.^{150,151} Advances in our understanding of the genetic determinants of surfactant metabolism and the development of sensitive diagnostic techniques have helped establish that inherited abnormalities of surfactant function are an important contributor to particular histologic signatures of ILD that were once classified as idiopathic (Table 77-6; Fig. 77-7).

As a group, the ILDs can be conceptualized as a diverse array of conditions arising from disordered alveolar repair following injury. The histopathologic features of the ILDs (see Table 77-6) help make clear that disruption in what would otherwise be a highly reliable program for regenerating the alveolar architecture appears to play a central role in the pathogenesis of ILD.¹⁵² Under favorable conditions, type II cells play a key role in repopulating the alveolar epithelial surface following local injury. After injury has taken place, surviving type II cells are capable of spreading over exposed basement membranes, proliferating, and even transdifferentiating into type I cells. Prolonged basement membrane exposure can alter the usual interactions between alveolar epithelial cells and mesenchymal cells, resulting in the maladaptive elaboration of cytokines, growth factors, oxidants, proteases, and antiapoptotic factors that encourage the proliferation of fibrillar collagen, elastic fibers, fibronectin, and proteoglycans.¹⁵² Nearby alveolar epithelial cells can actually translate this array of ambient molecular signals into a provocation compelling them to lose their apical-basal polarity, dissolve their intercellular adhesions, restructure their cytoskeleton, and assume a mesenchymal phenotype.^{152,153}

The highly metabolic nature of type II alveolar epithelial cells renders them vulnerable to dysfunction resulting from the cytoplasmic accumulation of mutant or dysfunctional proteins, which can be enough to overwhelm regulatory defenses and precipitate cell death.¹⁵² Surfactant synthesis and metabolism are key functions of the type II cell; the “life cycle” of surfactant is illustrated in Figure 77-7. Surfactant manufacture begins in the endoplasmic reticulum (ER), which is responsible for folding polypeptides into an appropriate geometric conformation to assure their proper function as mature proteins.

Surfactant protein C's (SP-C) polyvaline domain makes it particularly vulnerable to misfolding and aggregating into amyloid filaments.¹⁵² The C-terminal domain of its precursor molecule (pro-SP-C) mediates the folding process in a way that minimizes the tendency of the polyvaline domain to interfere with achievement of the proper SP-C protein conformation. Accordingly, mutations in the SP-C gene affecting the C-terminal domain of pro-SP-C can subvert this important adaptive function, setting the stage for cytoplasmic accumulation of aberrant protein material.¹⁵² In general, diseases causing accumulation of mutant proteins within the alveolar epithelial cell are well represented among the etiologic agents of pediatric ILD.

The Children's ILD (chILD) Research Cooperative recently proposed a novel classification scheme for pediatric ILD, based on pathologic specimens collected from 187 North American children less than 2 years of age who underwent lung biopsy between July 1999 and July 2004 for diffuse parenchymal disease.¹⁵⁶ The disease entities identified in this cohort ranged from primary congenital abnormalities of the alveolar-capillary unit, to acquired syndromes of chronic interstitial disease referable to infection, recurrent aspiration, or symptomatic cardiovascular disease (see Table 77-6).¹⁴⁶

Given the wide variety of potential etiologies in ILD, a systematic approach to the diagnostic workup is important.¹⁴⁸ While history and

FIGURE 77-7 ■ Surfactant production and metabolism. Surfactant proteins are manufactured in alveolar type II cells and Clara cells located on terminal bronchioles. Synthetic steps taking place within alveolar type II cells are shown. Surfactant synthesis begins in the endoplasmic reticulum, is further modified in the Golgi apparatus, and its components are stored in lamellar bodies until exocytosed into the alveolar space (step 5). There, surfactant forms a lattice (known as “tubular myelin”) that is transported to form a monolayer of surfactant film at the air-liquid interface. Surfactant phospholipids are engulfed and degraded by alveolar macrophages (step 8) or are shuttled back to type II cells for recycling (step 8). GM-CSF has an important role in surfactant homeostasis. Its interaction with a specific receptor triggers alveolar macrophage maturation to a degree that is required for efficient surfactant clearance. (Adapted from Han S, Mallampalli R. The role of surfactant in lung disease and host defense against pulmonary infections. *Ann Am Thorac Soc* 2015; 12:765-774.)

physical exam have a role in the initial evaluation of children with suspected ILD, noninvasive tests such as serologies, cultures, chest radiographs, high-resolution chest CT scans, pulmonary function testing, barium swallow, pH studies, and echocardiograms will more often allow the clinician to arrive at a specific diagnosis.^{147,148} In those children in whom an etiology is still unclear, more invasive studies such as bronchoalveolar lavage, cardiac catheterization, and lung biopsy should be considered.¹⁴⁸ Results of biopsy specimens may be important to guide decision making in critically ill children who are not responding to therapy.

Therapy

As many of the etiologies for pediatric ILD may begin with an inflammatory response to lung injury, treatment of children with this condition commonly involves the use of antiinflammatory agents such as corticosteroids. A favorable response to corticosteroids among children with ILD may be evident in only 40% of cases,¹⁵⁷ and this variability may reflect the diverse potential causes of the disease. In cases where concerns about long-term administration of corticosteroids arise,

steroid-sparing antiinflammatory agents such as azathioprine, cyclophosphamide, methotrexate, cyclosporine, and intravenous gamma globulin have been used.¹⁴⁷ There is also a great deal of experience with the use of hydroxychloroquine in the management of pediatric ILD, although its use has been associated with the development of hepatic toxicity and retinopathy in children.¹⁵⁷ For patients manifesting alveolar proteinosis, many demonstrate improvement following whole lung lavage.^{158,159} In keeping with its role in promoting surfactant clearance by triggering an appropriate level of alveolar macrophage maturation¹⁶⁰ (see Fig. 77-7), granulocyte monocyte-colony stimulating factor (GM-CSF) has been administered to these patients with some success,¹⁶¹ although patients with alveolar macrophage dysfunction on the basis of circulating GM-CSF antibodies present a particular therapeutic challenge.

■ COMPLEX PARENCHYMAL DISEASES

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is a term used to describe histopathologic changes in the lungs of neonates exposed to mechanical ventilation who go on to demonstrate radiologic abnormalities and supplemental oxygen dependence at 36 weeks' post menstrual age.¹⁶² Heterogeneous alveolar consolidation, squamous metaplasia of airway epithelium, hyperplasia of mucous glands, peribronchial fibrosis, airway smooth muscle hypertrophy, and vascular lesions of pulmonary hypertension typified BPD-related histopathologic changes when the disease was first described by Northway and colleagues in 1967.^{163,164} The past two decades have witnessed a shift in the histopathologic features of BPD away from cystic, metaplastic, and fibroproliferative changes toward a more uniform distribution of lung aeration across fewer, larger, and more simplified alveoli, with a concomitant impairment in the growth and development of the pulmonary microvasculature that often evolves into clinically significant pulmonary hypertension.^{165,166} Evolution of the BPD phenotype likely documents the effects from more than 20 years of widespread intratracheal surfactant administration to preterm infants, as well as a trend toward the use of lung-protective ventilatory strategies and other improvements in the supportive care of these patients. Fifteen years ago, a consensus conference refined the diagnostic criteria for BPD, reframing it as a disease with mild, moderate, or severe manifestations, depending on the intensity of respiratory support that an infant requires at the point of assessment (Table 77-7).¹⁶⁷ The revised criteria better represent the array of clinical manifestations seen in contemporary BPD and should facilitate the execution of clinical trials to identify subpopulations of infants who are likely to benefit from specific therapies. In the current era, BPD is most likely to develop in premature infants who are born at a gestational age when alveolar development is not yet complete whose birth weight ranges from below 1000 g to 1200 g.^{163,168} The National Institute of Child Health and Development (NICHD) Neonatal Research Network recently assembled a cohort of 9575 infants born between 2003 and 2007 at 22 to 28 weeks' gestational age and ranging in birth weight from 401 g to 1500 g. Using the newer severity-based diagnostic criteria, the investigators found a 68% incidence of BPD in these infants.¹⁶⁹

Clinically, the BPD syndrome is associated with airways hyperactivity and intermittent airway obstruction, leading to increased work of breathing, recurrent wheezing, chronic abnormalities of gas exchange, and potentially significant pulmonary hypertension.¹⁶³ Focal airway collapse consistent with tracheomalacia and/or bronchomalacia has also been documented in these infants,¹⁷⁰ and their pathogenesis in this context is not well understood. The spectrum of pathology observed in BPD patients is believed to derive from an inflammatory response to lung injury, as numerous investigations have identified mediators of inflammation in the BAL fluid of infants with chronic lung disease.¹⁷¹ Pulmonary edema from cardiogenic and noncardiogenic causes, infectious issues, and exposure to high concentrations of supplemental oxygen are other factors important in the pathogenesis

TABLE 77-7 Consensus Diagnostic Criteria for Bronchopulmonary Dysplasia (BPD)

| | | GESTATIONAL AGE | |
|---------------------------------|----------|---|--|
| | | <32 WEEKS | ≥32 WEEKS |
| Time point of assessment | | 36 weeks' post menstrual age or discharge to home* | >28 days but <56 days' postnatal age or discharge to home* |
| Supplemental oxygen requirement | | >21% for ≥28 days | >21% for ≥28 days |
| Disease severity | Mild | Breathing room air at 36 weeks' post menstrual age or at discharge* | Breathing room air by 56 days' postnatal age or at discharge* |
| | Moderate | Requires <30% oxygen at 36 weeks' post menstrual age or at discharge* | Requires <30% oxygen at 56 days' postnatal age or at discharge* |
| | Severe | Requires >30% oxygen, with or without mechanical ventilation or CPAP at 36 weeks' post menstrual age or at discharge* | Requires >30% oxygen with or without mechanical ventilation or CPAP at 56 days' postnatal age or at discharge* |

of BPD. Premature infants may be at special risk from exposure to high concentrations of supplemental oxygen because they are deficient in the antiproteases and antioxidant enzymes that have a role in modulating the injurious effects from the proliferation of reactive oxygen species.¹⁶²

While our present understanding of the pathogenesis of chronic lung injury in the neonate mirrors what has been learned from older children and adults, it is also important to recognize that in preterm infants, perinatally or postnatally acquired inflammatory lung injury takes place against a background of disrupted alveolar development. This is a key distinction between BPD and ARDS or acute lung injury that develops in mature infants and older children and likely accounts for the persistence of pulmonary morbidity in the BPD population into early adolescence.¹⁶⁶ In any event, preterm neonates with respiratory failure may be especially susceptible to ventilator-associated lung injury because surfactant deficiency, high chest wall compliance, and a dynamic FRC that is near closing capacity in this age group may potentiate cycles of derecruitment and reinflation that have been shown to promote the development of lung injury in humans and animal models, including surfactant-deficient preterm animals.^{136–138,172,173} Mechanical ventilatory techniques aiming to promote alveolar recruitment and maintain lung volume have in fact decreased the incidence of ventilator-associated lung injury in neonates. Numerous large prospective RCTs have found a lower incidence of chronic lung disease among high-risk infants supported with HFOV compared to cohorts who are supported with conventional phasic ventilation, with no apparent increase in the development of intracranial hemorrhage or other significant morbidities.^{174–176} A growing appreciation of the role of invasive mechanical ventilation in the pathogenesis of BPD has also created interest in whether the need for mechanical ventilatory support may be obviated through the strategic use of CPAP immediately after birth.^{177–180} The first studies showed that early initiation of CPAP and modest reductions of target oxygen saturations (91%–94%) could reduce the incidence of BPD.¹⁸¹ In a follow-up of this study, the NICHD Neonatal Research Network carried out an RCT involving 1316 neonates born at 24 to 28 weeks' gestational age.^{182,183} Using a 2 × 2 factorial design, the investigators compared (1) immediate intubation and surfactant administration against initiation of CPAP in the delivery room, allowing surfactant administration only for infants meeting predetermined criteria; and (2) target oxygen saturations of 85% to 89% against saturations of 91% to 95%. The first comparison tested the hypothesis that infants managed with early CPAP administration and adherence to a limited ventilation protocol would have a reduction in the incidence of BPD or death. The second tested the hypothesis that infants managed using a lower target saturation range would have a reduction in the incidence of severe retinopathy of prematurity or death. There were no significant differences between groups with respect to the first comparison, the rate of death or

development of BPD (defined as a supplemental oxygen requirement persisting to 36 weeks' corrected gestational age). Remarkably, 33% of infants in the early CPAP arm never received surfactant.¹⁸² Examining the impact of low versus high target saturations, the investigators found no difference between the groups in the composite primary outcome (rates of death or development of severe retinopathy). The incidence of BPD was also comparable between groups. However, while severe retinopathy developed less frequently among survivors in the low saturation group (8.6% vs. 17.9%; $P < 0.001$), death before discharge occurred more commonly among infants in this group (19.9% of the lower saturation group compared to 16.2% in the higher saturation group; $P = 0.04$).¹⁸³ While these results challenge the paradigm that intubation, surfactant administration, and commitment to a longer course of invasive ventilation are required elements of supportive care in preterm infants, they also raise an important note of caution that pursuing a strategy of moderate “permissive hypoxemia” does not appear to impact the incidence of BPD and may in fact reduce the incidence of severe retinopathy of prematurity at the expense of higher mortality.¹⁸³

Therapy

In the past 10 years, methylxanthines have emerged as having a potentially important role in the prevention of BPD. A large, multicenter RCT found that 36% of 963 very low-birth-weight infants who received caffeine in the first 10 days of life remained dependent on supplemental oxygen at 36 weeks postmenstrual age, compared to 47% in the placebo group ($P < 0.001$).¹⁸⁴ Positive pressure respiratory support was also discontinued 1 week earlier in the intervention group ($P > 0.001$). For those infants in whom BPD cannot be prevented, medications that may be useful in producing short-term improvements in their pulmonary mechanics include bronchodilators, corticosteroids, and diuretics.^{162,163,185} Aerosolized β agonists may be useful in the management of smooth-muscle mediated bronchospasm in infants with chronic lung disease, but the consequent decrease in airway smooth muscle tone may aggravate airway collapse in infants with tracheomalacia or bronchomalacia.¹⁷⁰ Diuretics may be especially helpful in the management of these infants because many demonstrate a tendency to accumulate fluid in the pulmonary interstitium on the basis of alterations in pulmonary vascular resistance, plasma oncotic pressure, capillary permeability, and impaired lymphatic drainage.¹⁷¹ Judicious use of diuretics can also facilitate the delivery of adequate nutrition to the infant with chronic lung disease.¹⁷¹ Inhaled nitric oxide (iNO) has also been studied for its potential role in treating refractory hypoxemia in infants with chronic lung disease. Case series have documented improvements in oxygenation with the use of iNO, even including infants with intercurrent infection, with a sustained response reported in some patients.^{186,187} Sildenafil (Revatio®, Pfizer, Inc., New York, NY) is an oral preparation that has been used for years as an off-label

adjunct therapy for managing BPD-related pulmonary hypertension. This drug selectively inhibits phosphodiesterase type 5, allowing the circulation of increased amounts of cyclic guanosine monophosphate, the second messenger in the molecular signaling cascade that triggers NO-induced vasorelaxation. Results from a 16-week clinical trial examining the use of sildenafil in treatment in naïve children aged 1 to 17 years pulmonary arterial hypertension ("STARTS-1")¹⁸⁸ aroused concerns that lower sildenafil doses did not show efficacy in improving exercise duration. As well, data emerging from the follow-up study suggested that children taking a higher dose of sildenafil may have a higher risk of death than those taking a lower dose.¹⁸⁹ In 2014, the FDA issued a recommendation on the matter, advising clinicians who remain inclined to offer sildenafil for treatment of children with PAH to consider whether the benefits of treatment outweigh its possible risks, on a case-by-case basis.^{191,192}

Lower respiratory tract infection is one of the most common reasons for hospital readmission in the first year of life for infants with BPD and accounts for a significant fraction of these pulmonary exacerbations.¹⁶⁸ Other potential causes for BPD exacerbations include aspiration syndromes, worsening pulmonary hypertension, and the evolution of clinically important systemic-to-pulmonary collateral vessels.¹⁶³ Therefore, the diagnostic approach to infants with BPD who demonstrate unexplained deterioration may include dynamic airway studies as well as echocardiography and, in certain cases, cardiac catheterization.¹⁶³ Treatment of these episodes is supportive and often includes empiric antibiotic coverage for potential infectious causes.

Congenital Diaphragmatic Hernia

Management of infants with congenital diaphragmatic hernia (CDH) is one of the greatest clinical challenge that the ICU clinician encounters. The Bochdalek hernia is the most common form and occurs when abdominal contents herniate into the thoracic cavity through a posterolateral diaphragmatic defect, usually at around the 10th week of gestation. This phase of gestation concurrently includes the branching of bronchi and pulmonary arteries, and this crucial process may be interrupted by the growing mass of herniated viscera.¹⁹³ On the other hand, the discovery that administering the teratogen nitrofen to midgestation rats results in diaphragmatic defects in the developing fetus as well as a spectrum of anomalies in other organ systems similar to what is seen in humans with CDH suggests that the pathogenesis of this syndrome may originate from fetal exposure to an agent that causes generalized maldevelopment from that point forward.¹⁹⁴⁻¹⁹⁷ Small animal models of CDH have since demonstrated that nitrofen disrupts fetal lung development by reducing fetal trophoblastic expression of retinol binding protein and transthyretin, proteins responsible for ushering maternal retinol into the fetal circulation, where it plays an important role in organ morphogenesis.¹⁹⁸

The complex pathology associated with CDH in humans includes a hypoplastic and abnormally muscularized pulmonary arterial tree.¹⁹³ Other congenital anomalies are associated with CDH in up to 39% of cases. Congenital cardiac disease is the most commonly associated feature and most frequently involves some degree of cardiac hypoplasia, although a wide variety of structural cardiac anomalies may be associated with CDH.¹⁹⁹ Genitourinary, gastrointestinal, neurologic, and skeletal defects are also commonly described.¹⁹³ Adjunct medical therapies have not managed to improve the survival of these infants, whose mortality rate is traditionally reported in the range of 50%. Nonetheless, there are experienced centers reporting more encouraging results in recent years by adopting strategic forms of mechanical support in these patients that incorporate much of what has been learned about modulating the pulmonary and hemodynamic consequences of mechanical ventilation.

Therapy

In infants with CDH, as in those with BPD, ICU management is directed at managing their lower airways disease, alveolar disease, and

abnormal pulmonary vascular reactivity. Initial medical stabilization of infants with CDH includes tracheal intubation and nasogastric decompression. It is preferable to obtain preductal (i.e., right radial) arterial access, when possible. Information from preductal blood gases should guide clinical intervention because it reflects the status of cerebral circulation. Initially, echocardiography is suggested to rule out structural cardiac disease, and it may be repeated as necessary throughout the clinical course to determine evidence of ongoing right-to-left shunting as well as estimates of right ventricular pressure and function in response to therapy.¹⁹³ iNO has been used with varying results, and a role for the drug in reducing the need for ECMO or in improving survival among these patients was not established by a large, RCT on the use of iNO in neonates with pulmonary hypertension.²⁰⁰ The evidence supporting the use of iNO in the management of infants with CDH is limited to small case series and individual case studies.²⁰¹⁻²⁰³ In CDH, as in BPD, deficient alveolar development may explain the limited potential benefit from iNO.¹⁸⁷ A limited number of reports have addressed the possibility of targeting an array of potential mechanisms behind pulmonary hypertension in CDH, including interference with calcium-mediated platelet activation and vasoconstriction (prostaglandin analogues), inhibition of endothelin-mediated vasoconstriction (bosentan), and inhibition of phosphodiesterase metabolism (sildenafil, milrinone), but none has been able to establish a clear outcome benefit for any of these agents in infants with this disease.²⁰⁴ At least one source has raised concern about the potential for hepatotoxicity when bosentan is used in infants.²⁰⁵

Recommendations for the optimal timing of surgical repair in infants with CDH have evolved over time. It was once considered appropriate to refer these infants for immediate repair. Growing experience with the mechanical support of CDH patients, along with the observation that pulmonary vascular resistance and reactivity as well as pulmonary compliance often become more favorable within days after birth, have since created a trend toward delaying surgical repair until a satisfactory level of physiologic stability can be achieved.^{193,206}

Mechanical Ventilation

Given what is presently known about ventilator-associated lung injury, it is logical to apply lung-protective ventilation strategies to infants with chronic lung disease as well as to infants with CDH. Although the technique has not been traditionally applied to neonates, permissive hypercapnia is in fact well tolerated by most infants with these conditions.²⁰⁷⁻²⁰⁹ Because of the heterogeneity of airspace involvement in BPD and CDH, regional hyperinflation can easily occur. Therefore, it makes sense to maintain end-expiratory lung volume with a careful titration of PEEP and limit tidal volume to 4 to 6 cc/kg in order to ventilate at the area of maximal compliance on the pressure-volume curve.²¹⁰ While managing these patients, monitoring of tidal volume at the endotracheal tube is important because compressible volume losses in the ventilator circuit can be significant. Judicious use of sedation and the use of spontaneous ventilation (such as flow-triggered pressure support) may improve matching of ventilation to perfusion and may allow optimal patient-ventilator synchrony.

A review of infants with CDH revealed a significant increase in survival from 44% to 69% during the period in which permissive hypercapnia was used to manage these infants, with even higher survival rates noted in infants without coexisting heart disease (Table 77-8).²¹¹ Neither the introduction of ECMO nor delaying surgical repair was associated with significant increases in survival in this single-center historic experience.²¹¹ Other case series have also reported favorable results using kinder and gentler ventilatory strategies, rather than more aggressive techniques that attempt to control pulmonary vascular resistance.^{206,212,213} These observations suggest that ventilator-associated lung injury contributes to excess mortality in infants with CDH,^{206,211} and it is possible that a survival benefit attributable to ECMO may emerge as lung-sparing mechanical ventilation is more widely applied.²¹¹ At least one single-center experience

suggests that epidural analgesia in the postoperative period facilitates spontaneous ventilation and may further improve pulmonary outcomes in these infants.²¹¹

Over the past decade, experience with the use of HFOV in infants with CDH has grown. For those clinicians who opt to use HFOV in this population, it is essential to understand that infants with CDH do not have inherently recruitable lungs, and attempts to improve gas exchange by applying high levels of mean airway pressure can increase the dead space fraction and may result in both lung injury and potentially dangerous elevations in pulmonary vascular resistance.²¹⁴ Therefore, centers experienced with the use of HFOV in infants with CDH generally recommend trying to limit the mean airway pressure to 16 cm H₂O or less.²¹⁴ The Hospital for Sick Children in Toronto has developed an HFOV protocol for infants with CDH that emphasizes maintaining a preductal SaO₂ of less than 85%, tolerating hypercarbia with a compensated pH, and initiation of HFOV when the peak inspiratory pressure on conventional ventilation exceeds 25 cm H₂O. Since implementing this set of guidelines in 1995, they have reported improvement in the survival of CDH infants.²¹⁴

WEANING THE PEDIATRIC PATIENT FROM MECHANICAL VENTILATION

Although it is clear that it is best to discontinue mechanical ventilatory support as soon as this is feasible, a great deal of controversy surrounds ventilator mode selection, the pace of weaning, and timing of separation from mechanical support in children. In the largest pediatric study presently available in the literature, the use of specific weaning modes and ventilator weaning protocols was evaluated against standard care (no defined ventilator weaning protocol) for mechanically ventilated infants and children.²¹⁵ Patients with alveolar disease as well as lower airways disease were included, while those less than 2 years of age with status asthmaticus and those with CDH were excluded. In this study, 182 intubated, spontaneously breathing children who met standardized bedside criteria for extubation readiness were randomized to the protocolized application of pressure support ventilation (PSV), volume support ventilation (VSV), or no protocol.²¹⁵ There were no significant differences among the three treatment groups in extubation failure rates, and most children were weaned from the ventilator in 2 days or less.²¹⁵ In children who were successfully extubated, the median duration of ventilator weaning did not significantly differ according to the mode of ventilation.²¹⁵ Separating infants or children with complex and/or chronic pulmonary disease from mechanical ventilation is challenging and requires an appreciation of the components of pulmonary dysfunction and timely recognition of acceptable mechanics and gas exchange in spontaneously breathing patients. For example, patients with alveolar hypoplasia are expected to be tachypneic at baseline, and this complicates the use of commonly applied criteria for extubation readiness. In these cases, weaning from mechanical

ventilation can be guided by an ongoing assessment of exhaled tidal volume (measured at the airway opening), work of breathing, serum pH, and evidence of appropriate daily weight gain as pressure support is decreased.

Numerous investigators have taken an interest in whether sedation practices in patients with acute respiratory failure could represent a potentially modifiable risk for extended dependence on mechanical ventilatory support. Studies carried out in adults have associated “dynamically managed” patient sedation protocols that seek to maintain a minimally sedated, spontaneously breathing patient with reductions in the duration of mechanical ventilation.²¹⁶⁻²²⁰ The recently published Randomized Evaluation of Sedation Titration for Respiratory Failure (RESTORE) trial evaluated whether a goal-directed, nurse-controlled sedation protocol would reduce the duration of mechanical ventilation in infants and children with acute respiratory failure.²²¹ This was a cluster randomized trial in which 31 participating U.S. PICUs were randomly designated as “intervention” sites, where sedation practices were strictly protocolized, or “usual care” sites (the control condition), where sedation practices and extubation readiness assessment remained discretionary. The trial enrolled 2449 children from 2 weeks to 17 years of age requiring invasive mechanical ventilation for acute airway and/or parenchymal disease. Intervention sites used a management protocol consisting of targeted sedation, routine arousal assessment, dynamic sedation titration, and extubation readiness testing. The study found no difference between the two PICU groups in the primary outcome, duration of mechanical ventilation (median 6.5 days [IQR 4.1–11.2 days] in intervention PICUs vs. median 6.5 [IQR 3.7–12.1 days] in control PICUs). The number of adverse events attributable to sedation practices (inadequate pain or sedation management, significant iatrogenic withdrawal, unplanned extubation or invasive line removal) was comparable in the two groups. Long-term follow-up is forthcoming.

CONCLUSION

A fundamental understanding of age-specific diagnostic and treatment considerations is required when caring for pediatric patients with pulmonary disease. Although the capacity for physiologic compensation in infants and children is remarkably efficient, they are also prone to sudden and profound clinical deterioration, warranting the application of sophisticated supportive measures in the ICU. In recent years, work in the laboratory as well as the clinical arena has brought about an appreciation that in airway disease, alveolar disease, and complex conditions such as BPD and CDH, gentler strategies of mechanical ventilation may have a central role in improving functional outcomes. Thoughtful application of therapies proven to reverse pulmonary pathophysiology while promoting spontaneous ventilation as much as possible is likely to enhance already favorable survival statistics for even the most critically ill pediatric patients.

Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. The Acute Respiratory Distress Syndrome Network. *N Engl J Med* 2000;342(18):1301-1308.

Landmark multicenter trial showing that in adult patients with ALI and ARDS ($PaO_2/FiO_2 \leq 300$), mechanical ventilation limiting tidal volumes to 6 cc/kg ideal body weight and plateau pressure ≤ 30 cm H₂O results in decreased mortality and more ventilator-free days when compared with tidal volumes of 12 cc/kg ideal body weight and plateau pressure ≤ 50 cm H₂O.

Courtney SE, Durand DJ, Asselin JM, Hudak ML, Aschner JL, Shoemaker CT. High-frequency oscillatory ventilation versus conventional mechanical ventilation for very-low-birth-weight infants. *N Engl J Med* 2002;347(9):643-652.

Large multicenter, well-controlled trial demonstrating significant benefit of HFOV compared to conventional ventilation in very low-birth-weight infants. Infants who received HFOV were successfully extubated earlier and were more likely to survive without need for supplemental oxygen at 36 weeks' postmenstrual age. No increase was observed in the occurrence of intracranial hemorrhage or other complications referable to prematurity.

Curley MA, Wypij D, Watson RS, Grant MJ, Asaro LA, Cheifetz IM, Dodson BL, Franck LS, Gedeit RG, Angus DC, et al: Protocolized sedation vs. usual care in pediatric patients mechanically ventilated for acute respiratory failure: a randomized clinical trial. *JAMA* 2015;313(4):379-389.

Multicenter cluster randomized trial in which 31 U.S. PICUs were randomly designated as "intervention sites" where a goal-directed, nurse-controlled sedation protocol was implemented for mechanically ventilated patients, or "usual care" sites, where sedation and extubation readiness assessment practices remained discretionary. The study found no differences between the two PICU groups in the primary outcome, the median number of days on mechanical ventilation. The number of adverse events attributable to sedation practices was comparable in the two groups. Long-term

follow-up assessing emotional outcomes and health care resource use in the two study arms will be forthcoming.

Ferguson ND, Cook DJ, Guyatt GH, Mehta S, Hand L, Austin P, Zhou Q, Matte A, Walter SD, Lamontagne F, et al: High-frequency oscillation in early acute respiratory distress syndrome ["OSCILLATE"]. *N Engl J Med* 2013; 368(9):795-805.

Multicenter, randomized controlled early intervention trial that enrolled 548 adult patients within 72 hours of meeting clinical criteria for moderate-severe ARDS to either HFOV (experimental condition) or conventional ventilation targeting a tidal volume of 6 cc/kg ideal body weight, plateau pressure ≤ 35 cm H₂O, and high PEEP (control condition). For patients randomized to HFOV, the initial mean airway pressure setting was 30 cm H₂O regardless of the mean airway pressure they required on conventional ventilation. Mean airway pressure was thereafter adjusted according to FiO_2 . To minimize tidal volume on HFOV, the maintenance frequency setting was the highest level that would allow arterial pH > 7.25 . Nearly half of the patients in each study arm had sepsis. This study was terminated early, after a planned interim analysis revealed that the HFOV group had an in-hospital mortality rate of 47% compared to 35% in the control group. As compared to their counterparts in the control arm, a significantly higher proportion of patients randomized to the HFOV group required vasoactive medications, neuromuscular blocking agents, and higher median doses of midazolam during the first week of the trial.

The Neonatal Inhaled Nitric Oxide Study Group (NINOS). Inhaled nitric oxide and hypoxic respiratory failure in infants with congenital diaphragmatic hernia. *Pediatrics* 1997;99(6):838-845.

Multicenter trial in which infants with isolated congenital diaphragmatic hernia and hypoxic respiratory failure were randomized to receive inhaled nitric oxide or 100% oxygen. The study was unable to show a survival benefit or reduction in need for extracorporeal membrane oxygenation among those infants who received nitric oxide.

DEFINITION AND CLINICAL MANIFESTATIONS

Acute coronary syndromes account for nearly 2 million hospitalizations annually in the United States, and if patients who die before reaching the hospital are included, the mortality may be as high as 25%. Acute coronary syndromes are a family of disorders that share similar pathogenic mechanisms and represent different points along a common continuum. They include ST elevation myocardial infarction (STEMI), non-ST segment elevation myocardial infarction (NSTEMI), and unstable angina (UA) pectoris. The common link among the various acute coronary syndromes is the rupture of a vulnerable, but previously quiescent, coronary atherosclerotic plaque. Exposure of the plaque contents to the circulating blood pool triggers the release of vasoactive substances and activation of platelets as well as the coagulation cascade. The extent of resultant platelet aggregation, thrombosis, vasoconstriction, and microembolization dictates the clinical manifestations of the syndrome.

Acute coronary syndromes have traditionally been classified into Q-wave myocardial infarction, non-Q-wave myocardial infarction (NQMI), and UA. More recently, the classification has shifted and has become based on the initial electrocardiogram; patients are divided into three groups: (1) those with ST-elevation (STEMI), (2) those without ST elevation but with enzyme evidence of myocardial damage (non-ST elevation MI or NSTEMI), and (3) those with UA. Classification according to a presenting electrocardiogram coincides with current treatment strategies since patients presenting with ST elevation benefit from immediate reperfusion and should be treated with fibrinolytic therapy or urgent revascularization. In contrast, fibrinolytic agents are not effective in other patients with acute coronary syndromes.

PATHOPHYSIOLOGY OF ACUTE CORONARY SYNDROMES

Myocardial ischemia results from an imbalance between oxygen supply and demand and usually develops in the setting of obstructive atherosclerotic coronary artery disease, which limits the blood supply. The pathophysiology of unstable coronary syndromes and myocardial infarction (MI) usually involves a dynamic partial or complete occlusion of an epicardial coronary artery because of acute intracoronary thrombus formation.

The inciting event underlying the development of acute coronary syndromes is the rupture of an atherosclerotic plaque.¹ The possible sequelae of plaque rupture include thrombus formation with a total occlusion and with STEMI, dissolution of the thrombus, and healing of the fissure, with clinical stabilization and subtotal occlusion, which can lead to either non-STEMI or UA.

Atherosclerotic plaques are composed of a lipid core, which includes cholesterol, oxidized low-density lipoproteins (LDLs), macrophages, and smooth muscle cells, covered by a fibrous cap. Plaque rupture occurs when external mechanical forces exceed the tensile strength of the fibrous cap. After plaque rupture, the clinical consequences depend largely on the balance between prothrombotic and antithrombotic forces.^{2,3} The lipid core contains tissue factors and other thrombogenic materials that lead to platelet activation and aggregation. Fibrinolytic

factors, such as tissue plasminogen activator, prostacyclin, and nitric oxide, act to counteract the potential for thrombosis. A major factor in the outcome of plaque rupture is blood flow. With a subtotal occlusion, high-grade stenosis, or vasospasm, a thrombus begins to propagate downstream in the arterial lumen. In contrast to the initial thrombi that are platelet rich, these thrombi contain large numbers of red cells enmeshed in a web of fibrin. The former would be expected to respond best to antiplatelet therapy and the latter to antithrombotic and fibrinolytic therapy.

STEMI

Epidemiology

STEMI comprises approximately 25% to 40% of MI presentations. In-hospital mortality and 1-year mortality rates from STEMI have decreased significantly with improvements in reperfusion therapy and guideline-directed medical therapy (GDMT); current in-hospital mortality can be as low as 4% to 6%, and 1-year mortality ranges from 7% to 18%.^{4,5} Nonetheless, not all eligible patients with STEMI receive reperfusion therapy; registry data from 2004 to 2006 estimated a miss rate of 7%, with the majority of those patients being elderly. Women, diabetics, and patients with renal disease appear to have worse outcomes when presenting with STEMI. Approximately 23% of patients with STEMI in the United States have diabetes mellitus, and three-fourths of all deaths among patients with diabetes mellitus are related to coronary artery disease. Patients with chronic renal disease, particularly those on dialysis, are less likely to receive GDMT; only 45% of eligible patients on dialysis received reperfusion therapy, and only 70% received aspirin on admission. At discharge, only 67% of patients on dialysis were prescribed aspirin, and only 57% were prescribed beta blockers.^{5,6} Women and patients on dialysis tend to have higher bleeding complications associated with antithrombotic therapy.^{6,7}

Diagnosis and Treatment of STEMI

Symptoms suggestive of MI may be similar to those of ordinary angina but are usually greater in intensity and duration. Nausea, vomiting, and diaphoresis may be prominent features, and malaise and even stupor attributable to low cardiac output can occur. Compromised left ventricular function may result in pulmonary edema with the development of pulmonary bibasilar crackles and jugular venous distention; a fourth heart sound can be present with small infarcts or even mild ischemia, but a third heart sound is usually indicative of more extensive damage.

A consensus group to standardize the definition of MI defines the changes diagnostic of STEMI as new ST elevation at the J-point in at least two contiguous leads of ≥ 2 mm (0.2 mV) in men or ≥ 1.5 mm (0.15 mV) in women in leads V2-V3, and ≥ 1 mm (0.1 mV) in other contiguous chest leads or the limb leads.^{7,8} However, there are several circumstances in which interpreting an ECG may be difficult. A new left bundle branch block (LBBB) has been referred to as a "STEMI equivalent" and has been treated. A multicenter, longitudinal study published in 2011 challenged this notion. In that study, 36/892 (4%) patients presenting with possible ACS had an LBBB presumed to be new, and of these, only 14 of the 36 were diagnosed with ACS.⁹ Similar

FIGURE 78-1 ■ Classification of recommendation and level of evidence. (From Gibbons RJ, Smith S, Antman E. American College of Cardiology/American Heart Association Clinical Practice Guidelines: Part I. C. Circulation. 2003;107:2979-2986.)

findings have been reported elsewhere.¹⁰ In the GUSTO-1 trial, of the 26,003 North American patients presenting with possible ACS, 131 (0.5%) with confirmed acute myocardial infarction had an LBBB.¹¹

Patients presenting with suspected myocardial ischemia should undergo a rapid evaluation, continuous monitoring, and reassessment. The 2013 ACCF/AHA Guidelines for the Management of ST-Elevation Myocardial Infarction emphasize the importance of choosing some type of reperfusion therapy as soon as possible when appropriate (Fig. 78-1). In addition to conventional antiplatelet therapy, an early decision to perform percutaneous coronary intervention (PCI), transfer to a PCI-capable facility, or administer fibrinolytic therapy should be made. The previous 2004 guidelines statement still holds: “the appropriate and timely use of some form of reperfusion therapy is likely more important than the choice of therapy.”¹² The current guidelines regarding reperfusion timing and strategy are listed in Table 78-1.

The 2013 ACCF/AHA Guidelines for the Management of STEMI emphasize the importance of early reperfusion by stating that for patients presenting to a non-PCI-capable hospital, every effort should be made to get that patient to a PCI-capable hospital within 120 minutes of first medical contact (FMC). In addition, EMS transport directly to a PCI-capable hospital for primary PCI is the recommended triage strategy for patients with STEMI, with an ideal FMC-to-device-time system goal of 90 minutes or less. See Figure 78-2 for the management of patients with STEMI who are candidates for reperfusion therapy.

Fibrinolytic Therapy

Early reperfusion of an occluded coronary artery is indicated for all eligible candidates. Overwhelming evidence from multiple clinical trials demonstrates the ability of fibrinolytic agents administered early in the course of an acute MI to reduce infarct size, preserve left ventricular function, and reduce short-term and long-term mortality.¹³⁻¹⁵ Patients treated early derive the most benefit.¹⁵ Fibrinolytics should be

TABLE 78-1

Strategy and Timing of Reperfusion Therapy for STEMI

| RECOMMENDATION | COR | LOE |
|--|-----|-----|
| Reperfusion therapy should be administered to all eligible patients with STEMI with symptom onset within the prior 12 hours | I | A |
| Primary PCI is the recommended method of reperfusion when it can be performed in a timely fashion by experienced operators | I | A |
| In the absence of contraindications, fibrinolytic therapy should be administered to patients with STEMI at non-PCI-capable hospitals when the anticipated first medical contact-to-device time at a PCI-capable hospital exceeds 120 minutes because of unavoidable delays | I | B |
| When fibrinolytic therapy is indicated or chosen as the primary reperfusion strategy, it should be administered within 30 minutes of hospital arrival | I | B |

considered within the first 12 hours of symptom onset when it is anticipated that primary PCI cannot be performed within 120 minutes from the FMC.⁶

Indications for and contraindications to fibrinolytic therapy are listed in Table 78-2. Because of the small, but nonetheless significant, risk of a bleeding complication (most notably, intracranial hemorrhage), the selection of patients with acute MI for the administration

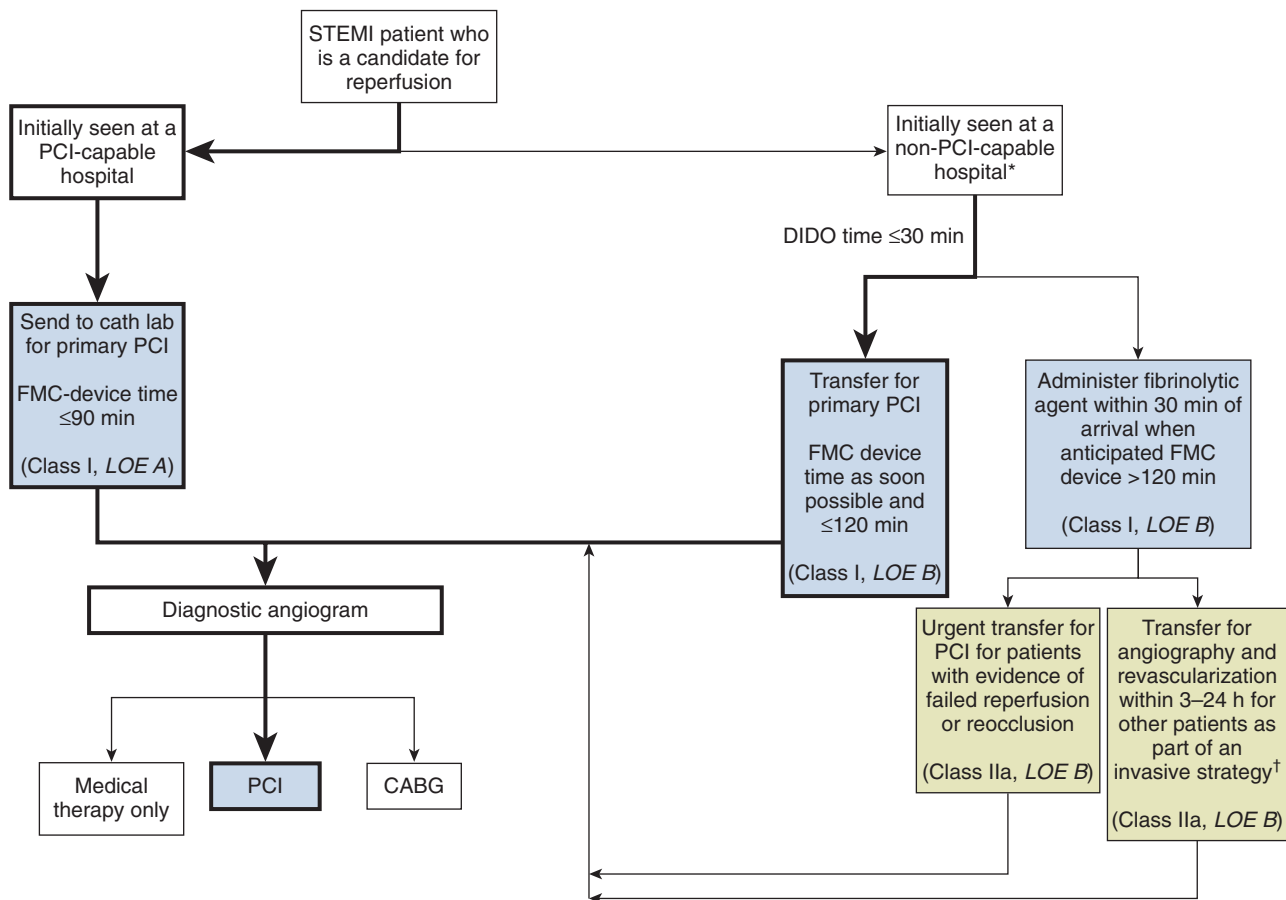

FIGURE 78-2 ■ Reperfusion therapy for patients with STEMI. (O’Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA Guidelines for the Management of ST-Elevation Myocardial Infarction: A Report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2013;127:e362-e425-27.)

of a fibrinolytic agent should be undertaken with prudence and caution. This is of special importance in ICU patients, who may have a predisposition to bleeding complications because of multiple factors. In this setting, emergent coronary angiography (with PCI as clinically indicated) is usually preferable.

Commonly administered fibrinolytics include the fibrin-specific agents tenecteplase, reteplase, and alteplase; the nonfibrin specific agent streptokinase is infrequently used. After the administration of fibrinolytics for STEMI, the patient should be monitored for signs and symptoms of adequate reperfusion, as indicated by relief of symptoms and/or hemodynamic/electrical instability coupled with the resolution of the highest initial ST elevation (preferably 50%, but at least some).^{16,17} Complete (or near complete) ST segment resolution at 60 or 90 minutes after fibrinolytic therapy is a useful marker of a patent infarct artery.¹⁸⁻²⁰ If signs of adequate reperfusion are not evident within 90 minutes (“failed fibrinolysis”), patients should be urgently transferred to a PCI-capable facility.⁶ Patients with STEMI and signs of shock or severe heart failure should be immediately transferred to a PCI-capable facility irrespective of when the MI occurred or when fibrinolytics were given.²¹ Diagnostic coronary angiography and possible PCI within 3 to 24 hours after fibrinolytics are given is referred to as a pharmacoinvasive strategy and should be considered, even if there is evidence of reperfusion and the patient remains hemodynamically stable. This recommendation is supported by case-control studies and randomized controlled trials with small sample sizes that showed a reduction in death, recurrent MI, recurrent ischemia, new or worsening HF, or shock at 30 days with routine angiography compared to patients who

underwent an ischemia-guided approach to coronary angiography after fibrinolysis.²²⁻²⁴

The greatest benefit from angioplasty following fibrinolysis is seen in high-risk patients. This is likely driven by a reduction in the incidence of a recurrent infarction or ischemia.^{25,26} In contrast to the treatment of STEMI, fibrinolysis has shown no benefit and an increased risk of adverse events when used for the treatment of UA/NSTEMI.²⁷ Based on these findings, there is currently no role for fibrinolytic agents in these latter syndromes.

Primary PCI in Acute Myocardial Infarction

The major advantages of primary PCI over fibrinolytic therapy include a higher infarct artery patency, with a higher rate of normal flow, lower rates of recurrent ischemia, reinfarction, the need for emergency repeat revascularization, and a lower risk of intracranial hemorrhage.^{14,28} Coronary angiography also affords the ability to stratify risk based on the severity and distribution of coronary artery disease. Data from several randomized trials have indicated that PCI is preferable to fibrinolytic therapy for AMI patients at a higher risk.²⁸

More important than the method of revascularization is the time to revascularization and that this should be achieved in the most efficient and expeditious manner possible.²⁹ It is important to keep in mind that early, complete, and sustained reperfusion after myocardial infarction is known to decrease the 30-day mortality rate. The preferred method for reperfusion in STEMI is PCI if it can be done in a timely manner, defined as the first contact to device time of less than 90

TABLE 78-2

Indications for and Contraindications to Fibrinolytic Therapy in ST Elevation Myocardial Infarction

INDICATIONS FOR FIBRINOLYTIC THERAPY WHEN THERE IS A >120-MINUTE DELAY FROM FIRST MEDICAL CONTACT TO PRIMARY PCI

- Presentation within 12 hours of symptom onset
- Evidence of ongoing ischemia 12 to 24 hours after symptom onset, and a large area of myocardium at risk or hemodynamic instability
- Fibrinolytics are contraindicated for the treatment of ST depression (NSTEMI), except if true posterior myocardial infarction or when associated with ST elevation in lead aVR

CONTRAINDICATIONS

Absolute

- Any prior ICH
- Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months (EXCEPT acute ischemic stroke within 4.5 hrs)
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head or facial trauma within 3 months
- Intracranial or intraspinal surgery within 2 months
- Severe uncontrolled hypertension (unresponsive to emergency therapy)
- For streptokinase, prior treatment within the previous 6 months

Relative

- History of chronic, severe, poorly controlled hypertension
- Significant hypertension on presentation (SBP >180 mm Hg or DBP >110 mm Hg)
- History of prior ischemic stroke >3 mo
- Dementia
- Known intracranial pathology not covered in absolute contraindications
- Traumatic or prolonged (>10 min) CPR
- Major surgery (<3 wk)
- Recent (within 2 to 4 wk) internal bleeding
- Noncompressible vascular punctures
- Pregnancy
- Active peptic ulcer
- Oral anticoagulant therapy

CPR, cardiopulmonary resuscitation; MI, myocardial infarction; PCI, percutaneous coronary intervention.

minutes. If a patient initially presents to a non-PCI-capable hospital and door in–door out time is anticipated to be less than 30 minutes, then the transfer to a PCI-capable hospital should be arranged if the FMC to device time is anticipated to be less than or equal to 120 minutes. If the FMC to device time is longer than 120 minutes, fibrinolytics should be considered, with probable transfer to a PCI-capable facility following fibrinolytic therapy for STEMI. Practical considerations regarding transport to a PCI-capable facility should be reviewed carefully before foregoing thrombolytics for PCI. Achieving reperfusion in timely matter correlates with improvement in the ultimate infarct size, left ventricular function, and survival.^{16,17} The ultimate goal is to restore adequate blood flow through the infarct-related artery to the infarct zone, as well as to limit microvascular damage and reperfusion injury. The latter is accomplished with adjunctive and ancillary treatments that will be discussed below.

Coronary Stenting

Primary balloon angioplasty for acute myocardial infarction results in a significant reduction in mortality but is limited by the possibility of an abrupt vessel closure, recurrent in-hospital ischemia, reocclusion of the infarct-related artery, and restenosis. The use of coronary stents has been shown to reduce restenosis and adverse cardiac outcomes in both routine and high-risk PCI and has now become routine in acute coronary syndromes.³⁰ Whether to use a bare metal stent or a drug-eluting

stent in acute MI is a question that has not yet been addressed definitively by clinical trials; selection is currently based on both patient and angiographic characteristics. Restenosis rates are lower with drug-eluting stents, and with advances in technology, stent thrombosis rates are decreasing. In patients with a high bleeding risk, the inability to comply with 1 year of dual antiplatelet therapy (DAPT), or anticipated invasive or surgical procedures in the next 1 year, bare metal stents are preferred.⁶

Adjunctive Therapy to Primary PCI

Aspirin

Aspirin is the best known and the most widely used of all the antiplatelet agents because of the low cost and relatively low toxicity. Aspirin inhibits the production of thromboxane A₂ by irreversibly acetylating the serine residue of the enzyme prostaglandin H₂ synthetase. Aspirin has been shown to reduce the mortality in acute infarction to the same degree as fibrinolytic therapy, and its effects are additive to fibrinolytics.³¹ In addition, aspirin reduces the risk of reinfarction.^{32,33} Unless contraindicated, all patients with a suspected acute coronary syndrome (STEMI, NSTEMI, UA) should be given aspirin as soon as possible. A 162- to 325-mg dose should be given initially. The maintenance dose is typically 81 mg daily, and aspirin should be continued indefinitely unless contraindicated.

Adenosine Diphosphate Receptor P2Y₁₂ Blockers

P2Y₁₂ inhibitors include clopidogrel, prasugrel, and ticagrelor. A loading dose of a P2Y₁₂ receptor inhibitor should be given as early as possible or at time of primary PCI to patients with STEMI.⁶

Clopidogrel is a pro-drug that is converted in the liver to the active thiol metabolite via the cytochrome P450 (CYP) 3A, 1A, 2B, and 2C subfamilies. The active metabolite binds irreversibly to the P2Y₁₂ component of the ADP receptor on the platelet surface, preventing the activation of the GPIIb/IIIa receptor complex and reducing platelet aggregation for the remainder of the platelet's lifespan, which is approximately 7 to 10 days. The onset of the inhibition of platelet aggregation (IPA) is dose-dependent, with a 300 to 600-mg loading dose achieving the inhibition of platelets within 2 hours. A 600-mg loading dose of clopidogrel provides more rapid platelet inhibition and is preferred to a 300-mg loading dose.³⁴

Prasugrel is a thienopyridine that irreversibly binds to the P2Y₁₂ component of the ADP receptor with a more rapid onset of action.⁴¹ Like clopidogrel, prasugrel is a prodrug metabolized to both an active and inactive metabolite, but a higher proportion is metabolized to an active metabolite, resulting in a higher level of inhibition of platelet aggregation than clopidogrel. The onset of inhibition of platelet aggregation is dose-dependent and can be achieved in less than 30 minutes with a loading dose of 60 mg, but peak effect occurs in approximately 4 hours.⁴² In the randomized, double-blind TRITON-TIMI 38 trial, patients treated with prasugrel had a significant reduction in nonfatal MI when compared to those treated with clopidogrel.⁴³ The rate of major bleeding was higher in the prasugrel group (2.4% vs. 1.8%, $P = 0.03$), as was the rate of life-threatening bleeding. A post hoc analysis of the TRITON-TIMI 38 trial identified either harm or no benefit in patients with a history of TIA or stroke (net harm), age over 75 years (no net benefit), and body weight less than 60 kg (no net benefit). The FDA has labeled a history of TIA and/or stroke as a contraindication to prasugrel use.⁴⁴

Ticagrelor is a reversible, nonthienopyridine P2Y₁₂ receptor antagonist that does not require metabolic conversion to the active drug. The PLATO trial compared ticagrelor to clopidogrel in 18,000 patients presenting with ACS, 38% of whom had a STEMI; the primary endpoint (MI, stroke, or cardiovascular death) occurred less often with ticagrelor (9.4% vs. 10.8%, $P < 0.05$), although there were more strokes and episodes of intracranial hemorrhage with ticagrelor.⁴⁵ Interestingly, ticagrelor was less effective in North America than in the rest of the world, probably due to an interaction with the aspirin maintenance dose (more patients in the United States took a median aspirin dose

≥300 mg/dL).⁴⁶ Hence, when a ticagrelor is used with aspirin as a component of dual antiplatelet therapy, the dose of aspirin should not exceed 100 mg.⁴⁷

Dual antiplatelet therapy with aspirin and P2Y₁₂ inhibition is given to all patients undergoing PCI, as described above. However, data suggest that even patients not undergoing PCI benefit from the addition of clopidogrel to aspirin.⁴⁸ On the basis of these data, patients presenting with MI should be considered for clopidogrel regardless of whether or not they underwent reperfusion therapy. Ticagrelor and prasugrel have not been evaluated in STEMI patients treated with fibrinolysis, and there is concern about the potential for increased bleeding in this patient population.⁵⁰

Glycoprotein IIb/IIIa Receptor Antagonists

Glycoprotein IIb/IIIa receptor antagonists inhibit the final common pathway of platelet aggregation, blocking the crosslinking of activated platelets, and are often used as percutaneous interventions.⁵¹⁻⁵⁴ In the era of dual antiplatelet therapy using P2Y₁₂ inhibitors and aspirin, the role of the addition of a glycoprotein IIb/IIIa inhibitor in primary angioplasty for STEMI is uncertain. “Upstream” (prior to PCI) use of a GP IIb/IIIa receptor antagonist has failed to show benefit and is no longer recommended. Current guidelines suggest that when a patient with an ST elevation MI is treated with a thienopyridine and aspirin plus an anticoagulant, such as UFH or bivalirudin, the use of a glycoprotein IIb/IIIa inhibitor at the time of PCI cannot be recommended as routine but may be beneficial and is typically considered on an individual patient basis. For example, the use of a glycoprotein IIb/IIIa inhibitor at the time of PCI may be appropriate if the patient has a large thrombus burden or if there was insufficient loading with a P2Y₁₂ receptor antagonist.⁵⁵

Anticoagulants in Patients Undergoing PCI

For patients undergoing PCI who have already been treated with aspirin and a P2Y₁₂ inhibitor, both unfractionated heparin and bivalirudin are acceptable anticoagulant regimens.⁵⁵ Bivalirudin is a direct thrombin inhibitor that inhibits both clot-bound and circulating thrombin. It is an alternative to unfractionated heparin in patients with a history of heparin-induced thrombocytopenia. Previous studies have concluded that bivalirudin is at least equivalent to heparin plus a glycoprotein IIb/IIIa inhibitor in reducing ischemic events.⁶⁰⁻⁶² More recent trials which reflect contemporary practices such as DAPT use, a radial approach to PCI, and decreased use of IIb/IIIa glycoprotein inhibitors, have concluded that compared to bivalirudin, heparin reduces the incidence of major adverse ischemic events in the setting of primary PCI, with no increase in bleeding complications.⁶³ See [Table 78-3](#) for doses of antiplatelet and anticoagulant therapy for the management of STEMI.

Coronary Artery Bypass Graft (CABG) Surgery in Patients with STEMI

Subsets of patients who present with STEMI are better served with CABG. Patients with failed PCI or whose coronary anatomy is not amenable to PCI but who have ongoing symptoms of ischemia, cardiogenic shock, severe HF, or other high-risk features should be considered for CABG.⁶⁵ CABG is also recommended in patients who require not only revascularization but also the repair of a mechanical defects, such as a ventricular septal defect, free wall rupture, or papillary muscle rupture.⁶ The previously reported increased mortality in CABG patients who recently had a STEMI needs to be balanced against the need for revascularization. Consideration must be given to the timing of urgent CABG in relation to the administration of antiplatelet agents in patients with a recent STEMI. [Table 78-4](#) provides a summary of these recommendations. The risk of major bleeding and mediastinal reexploration was previously reported to be quite high in patients who had received clopidogrel 5 to 7 days before CABG. However, a 2009 trial with randomized patients to clopidogrel either continued until the day of CABG, stopped 3 days before CABG, or stopped 5 days

TABLE 78-3

Adjunctive Antiplatelet and Anticoagulant Therapy to Support Reperfusion with Primary PCI

| DRUG | DOSING | COR | LOE |
|---|--|----------|-----|
| ANTIPLATELET THERAPY | | | |
| Aspirin | 162-325 mg loading 81 mg maintenance | I | B |
| Clopidogrel | 600 mg loading 75 mg maintenance | I | B |
| Prasugrel | 60 mg loading 10 mg maintenance | I | B |
| Ticagrelor | 180 mg loading 90 mg twice a day maintenance | I | B |
| GP IIb/IIIa RECEPTOR ANTAGONISTS IN CONJUNCTION WITH UFH OR BIVALIRUDIN IN SELECTED PATIENTS | | | |
| Abciximab | 0.25-mg/kg IV bolus, then 0.125 mcg/kg/min (maximum 10 mcg/min) | IIA | A |
| Tirofiban | 25-mcg/kg IV bolus, then 0.15 mcg/kg/min CrCl < 30 mL/min, reduce infusion by 50% | IIA | B |
| Eptifibatide | 180-mcg/kg IV bolus, then 2 mcg/kg/min; a second 180-mcg/kg bolus is administered 10 min after the first bolus CrCl < 50 mL/min, reduce infusion by 50% Avoid in patients on hemodialysis | IIA | B |

before CABG demonstrated a significant increase in bleeding and blood product utilization only in the group who continued clopidogrel until the day of surgery. Those whose clopidogrel was held either 3 or 5 days in advance had a similar rate of major bleeding, which was low and comparable to historical controls.⁶⁶ Retrospective, nonrandomized studies have reported similar rates of CABG-related bleeding in comparable patients receiving either clopidogrel or ticagrelor prior to surgery.⁶⁷ A subset of subjects in the TRITON-TIMI 38 studies who had CABG after STEMI as opposed to PCI had a significantly increased rate of TIMI minor and major bleeding after CABG surgery (21.9% vs. 4.1%, $P < 0.004$).⁶⁸ This should be taken into consideration when choosing a P2Y₁₂ receptor antagonist in STEMI patients who may need CABG.

Other Medical Therapies

Nitrates

Nitrates have a number of beneficial effects in acute myocardial infarction. They reduce myocardial oxygen demand by decreasing preload and afterload and may also improve myocardial oxygen supply by increasing subendocardial perfusion and collateral blood flow to the ischemic region.⁶⁹ Patients with ST elevation due to an occlusive coronary artery spasm may have a dramatic resolution of ischemia with nitrates. In addition to their hemodynamic effects, nitrates also reduce platelet aggregation. Despite these benefits, the GISSI-3 and ISIS-4 trials failed to show a significant reduction in mortality from routine acute and chronic nitrate therapy.^{70,71} Nonetheless, nitrates remain the first-line agents for the symptomatic relief of angina pectoris and when a myocardial infarction is complicated by hypertension or congestive heart failure. Nitrates should be avoided in patients with right ventricular infarct, hypotension (SBP < 90 mm Hg or if the SBP is > 30 mm Hg below baseline), or phosphodiesterase-5-inhibitor use within the previous 24 to 48 hours.

Beta Blockers

Beta blockers are beneficial both in the early management of myocardial infarction and as long-term therapy. In the prethrombolytic era, early intravenous atenolol was shown to significantly reduce reinfarction, cardiac arrest, cardiac rupture, and death.⁷² However, more recent data have shown that while the early administration of intravenous beta blockers followed by oral dosing may lower the reinfarction rate at 4 weeks, there may be an increase in the risk of developing heart failure and cardiogenic shock when compared to the placebo.⁷³ Based on these findings, routine use of intravenous beta blockers in the absence of systemic hypertension is no longer recommended.⁷⁴ However, oral beta blockers should be administered to patients within the first 24 hours of having a STEMI as long as the following conditions are not present: signs of heart failure; cardiogenic shock or a low-output state; significant AV conduction disease; or active wheezing due to reactive airway disease.⁶ Unless contraindicated, beta blockers should be continued beyond the hospitalization.

Renin-Angiotensin-Aldosterone System (RAAS) Inhibitors

The RAAS inhibitors include angiotensin converting enzyme inhibitors (ACE-I), angiotensin receptor blocker (ARB), and aldosterone antagonists.

Immediate intravenous ACE inhibition, particularly with enalaprilat, has not been shown to be beneficial,⁸⁰ but oral ACE inhibition should be started early in the hospital course. An ACE-I should be administered within the first 24 hours to all patients with a STEMI and LV dysfunction or heart failure.⁶ Possible contraindications to ACE-I use include hypotension, shock, or a history of renal failure or hyperkalemia with ACE-I or ARB use. Baseline renal function should be taken into consideration when initiating an ACE or and ARB, but renal failure is not an absolute contraindication to their use. Patients should be started on low doses of oral agents and titrated to maximally tolerated doses. STEMI patients who are intolerant to

an ACE-I should be given an ARB. In particular, valsartan has been shown to be noninferior to captopril in the VALIANT (Valsartan in Acute Myocardial Infarction) trial.⁸¹ Aldosterone has also been implicated in deleterious LV remodeling after MI. Early initiation (<7 days post MI) of the aldosterone antagonist eplerenone has a proven mortality benefit and should be given to patients with STEMI and no contraindications who are already receiving an ACE inhibitor and beta blocker and who have an EF less than or equal to 40% and either symptomatic HF or diabetes mellitus.^{6,82} Contraindications to the use of an aldosterone antagonist include creatinine greater than 2.5 mg/dL in men and more than 2.0 mg/dL in women or potassium higher than 5.0 mEq/L.

Lipid-Lowering Agents

Multiple studies have shown that statin use in patients after ACS can prevent death, recurrent MI, and stroke.^{83,84} Use of a high-intensity statin is preferred and should be initiated before discharge to improve compliance.^{5,6} In patients with ACS, high-intensity statin therapy should be given regardless of the LDL level. Among the currently available statins, only high-dose atorvastatin (80 mg daily) has been shown in clinical trials to reduce death and ischemic events among patients with ACS.^{85,86} Contraindications to statin use include a history of statin-induced rhabdomyolysis or significant myopathy and/or acute liver injury.

Calcium Channel Blockers

Randomized clinical trials have not demonstrated that routine use of calcium channel blockers improves survival after myocardial infarction.⁸⁷ In fact, meta-analyses suggest that high doses of the short-acting dihydropyridine nifedipine increased mortality in myocardial infarction.⁸⁸ Adverse effects of calcium channel blockers include bradycardia, atrioventricular block, and an exacerbation of heart failure.

Oxygen

The routine use of oxygen in patients with ACS who are not hypoxic (oxygen saturation <90%) is no longer recommended. A pooled Cochrane analysis of 3 trials showed no mortality benefit when supplemental oxygen was given to normoxic patients with confirmed MI and even suggested possible harm (increased mortality) from routine oxygen use.⁹⁰ The AVOID trial randomized 441 patients with confirmed STEMI to supplemental oxygen or none regardless of oxygen saturation. In patients who received supplemental oxygen, there was an increase in the rate of recurrent myocardial (5.5% vs. 0.9%, $P = 0.006$) and an increase in the frequency of cardiac arrhythmia (40.4% vs. 31.4%; $P = 0.05$). At 6 months, the oxygen group had an increase in the myocardial infarct size on CMR ($n = 139$; 20.3 g vs. 13.1 g; $P = 0.04$). Supplemental oxygen therapy in patients with STEMI but without hypoxia is no longer recommended.⁹¹

UA AND NSTEMI

UA and NSTEMI should be considered as part of the spectrum of ACS with elevated cardiac troponin differentiating NSTEMI from UA. The key to the initial management of patients with acute coronary syndromes who present without ST elevation is risk stratification. The overall risk of a patient is related to both the severity of preexisting heart disease and the degree of plaque instability. Risk stratification is an ongoing process, which begins with hospital admission and continues through discharge (see Fig. 78-3).

The risk of acute coronary syndromes increases with age. ST segment depression on the electrocardiogram identifies patients at a higher risk for clinical events.⁹² However, a normal 12-lead ECG does not exclude an NSTEMI and is seen in approximately 1% to 6% of patients with ACS.^{93,94} For example, a left circumflex coronary artery occlusion can be “electrically silent” and may only be detected using posterior leads V7-V9. An isolated posterior infarction can occur with a left circumflex or right coronary artery occlusion and manifest as tall R waves in the anterior leads V1-V3; ST elevation may be seen in

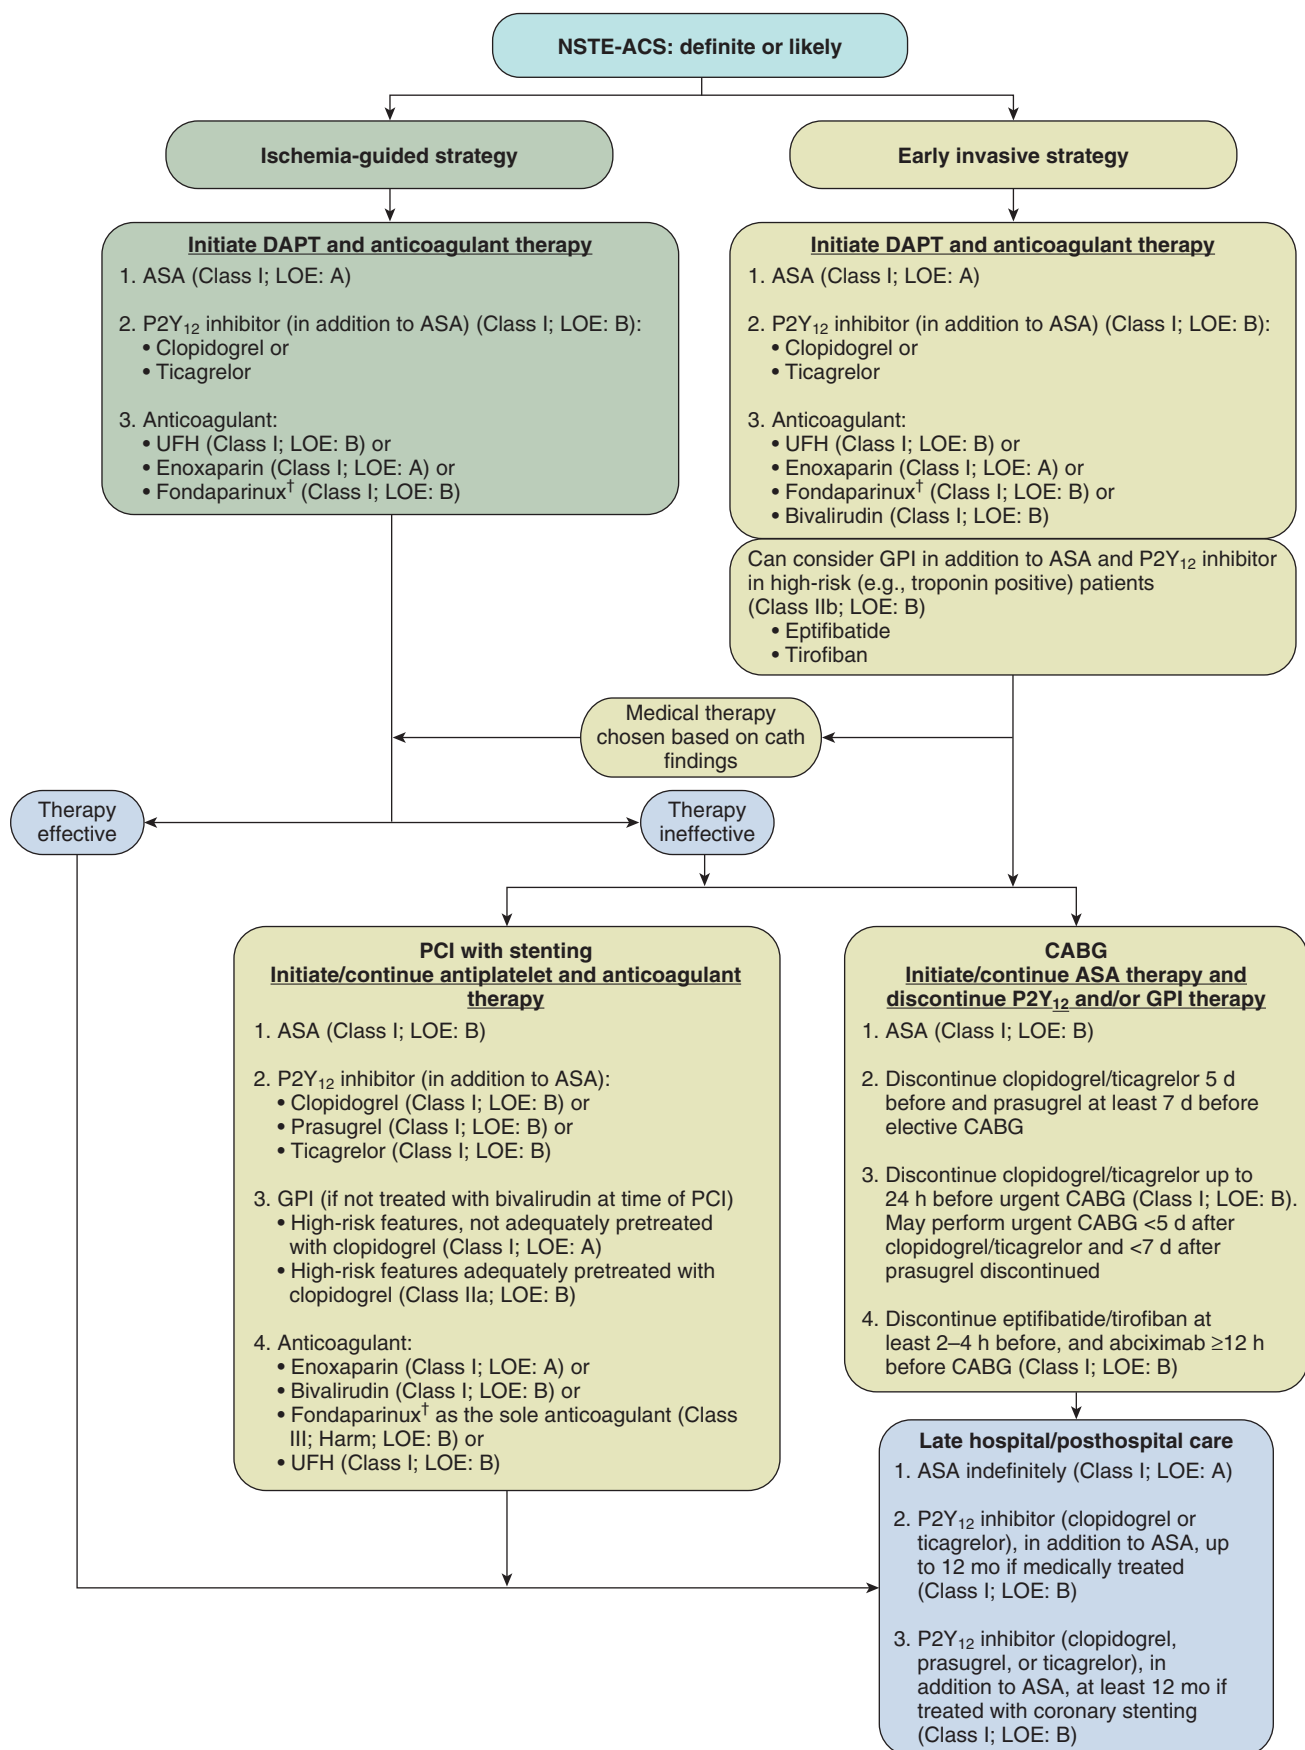

FIGURE 78-3 ■ Algorithm for management of patients with definite or likely NSTEMI-ACS. (From Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC Guidelines for the Management of Patients With Non-ST-Elevation Acute Coronary Syndromes: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation. 2014;130:e344-426.)

TABLE 78-5 Non-ACS Causes of ST-T Wave Changes on ECG

| DISEASE/CONDITION | ECG FINDING |
|-------------------------------|--|
| Left ventricular aneurysm | ST elevation in precordial leads, Q waves, TWI (low amplitude) |
| Pericarditis or myocarditis | Widespread concave ST elevation and PR depression throughout most of the leads. Reciprocal ST depression and PR elevation in lead aVR (\pm V1) |
| Right bundle branch block | ST depressions and T wave inversions in the right precordial leads |
| Left ventricular hypertrophy | Down-sloping ST segments into an inverted T wave in the lateral leads ("LV strain pattern") ST elevations and tall positive T waves are also common findings in leads V1 and V2 |
| Hyperkalemia | Peaked T waves |
| Prinzmetal angina | ST elevation in an anatomic distribution |
| Stress-induced cardiomyopathy | ST elevation |
| Brugada pattern | ST elevation in V1-V3 |
| CNS disease | Deep T wave inversions ST depression |
| Early repolarization | J-point elevation of ≥ 0.1 mV in two adjacent leads Widespread concave ST elevation, most prominent in the mid- to left precordial leads (V2-V5) No reciprocal ST depression to suggest STEMI (except in aVR) |

posterior leads (V7-V9) but typically does not exceed 1 mm. If there is a high clinical suspicion for ACS, a repeat ECG should be done in 15- to 30-minute intervals for the first hour.⁹⁵ Nonspecific ST and T wave changes can be seen on ECG in the absence of ACS. See Table 78-5 for non-ACS causes of ST-T wave changes.

Cardiac Biomarkers in NSTEMI

Biochemical markers of cardiac injury are predictive of outcome. The preferred biomarker for the diagnosis of myocardial necrosis is troponin. Cardiac troponin T and cardiac troponin I are sensitive markers of cardiac injury, particularly when used with the recommended diagnostic cut point of the 99th percentile of healthy controls.^{96,97} Elevated levels of troponin T are associated with an increased risk of cardiac events and a higher 30-day mortality.⁹⁸ Conversely, low levels are associated with low event rates, although the absence of troponin elevation does not guarantee a good prognosis and is not a substitute for good clinical judgment. Troponins are elevated in MI as early as 2 to 4 hours after symptom onset and may persist for several days after the initial event.

An elevated cardiac troponin level in the absence of overt ischemic heart disease is a common finding in both acute and nonacute processes. When serum cardiac troponin is present but the clinical information does not suggest ACS, the clinician should look for other causes.

Early Invasive Approach Versus Ischemia-Guided Approach to Treatment of NSTEMI

Two pathways have emerged in the management of patients with an NSTEMI and are referred to as an *early invasive approach* or an *ischemia-guided approach*. An early invasive approach is defined as a coronary angiogram within 24 hours of admission with PCI if

appropriate. An early invasive approach is clearly indicated in patients with NSTEMI who have refractory angina, hemodynamic or electrical instability, severe heart failure, or worsening mitral regurgitation and who lack serious comorbidities or contraindications to performing cardiac catheterization.⁹⁵ An early invasive strategy should not be considered for patients who are deemed low risk or who have significant comorbidities such as bleeding, advanced liver or renal failure, end-stage lung disease, or advanced-stage cancer such that the risk of PCI outweighs the benefit. Whenever considering an invasive strategy, the patient's ability to tolerate anticoagulation, antiplatelet, or antithrombotic therapy must be considered.

Risk stratification is the key to managing patients with NSTEMI acute coronary syndromes. An initial strategy of medical management with attempts at stabilization is warranted in patients with a lower risk, but patients at higher risk should be considered for cardiac catheterization.

Guideline-Directed Medical Therapy for UA/NSTEMI

Standard medical therapy for the early management of patients presenting with UA/NSTEMI includes analgesics, nitrates, and antiplatelet and antithrombotic therapy. Other medications that should be considered include high-dose statin, beta blockers, and renin angiotensin blockers. See Table 78-6 for a summary of recommendations for the use of medications in UA/NSTEMI.

Initial Antiplatelet/Anticoagulant Therapy in Patients with Definite or Likely NSTEMI

Antiplatelet Therapy

Antiplatelet therapy includes aspirin, P2Y₁₂ receptor inhibitors, and glycoprotein IIb/IIIa inhibitors. As previously noted, aspirin is a mainstay of therapy for acute coronary syndromes. A loading dose of 162 mg to 325 mg non-enteric-coated aspirin is the initial antiplatelet therapy. Both the VA Cooperative Study Group^{32,99} and the Canadian Multicenter Trial¹⁰⁰ showed that aspirin reduces the risk of death or myocardial infarction by approximately 50% in patients with UA or NSTEMI. Aspirin also reduces events after resolution of an acute coronary syndrome, and 81 mg should be continued indefinitely. In patients who are aspirin-intolerant (allergy or significant GI intolerance), a loading dose of clopidogrel followed by a daily maintenance dose should be administered.⁶

Similar to patients with STEMI, patients with NSTEMI and UA benefit from the use of P2Y₁₂ receptor inhibitors, in addition to aspirin. This benefit, a decrease in cardiovascular death, MI, or stroke, is seen not only in patients who undergo PCI but also in patients who are managed medically.¹⁰¹ This benefit may come with a 1% absolute increase in major, non-life-threatening bleeds ($P = 0.001$) as well as a 2.8% absolute increase in major/life-threatening bleeds associated with CABG within 5 days ($P = 0.07$) as seen in the CURE trial.¹⁰¹ Patients undergoing PCI in this trial had a 31% reduction in cardiovascular death or MI ($P < 0.002$)¹⁰²; however, because PCI was performed in only 23% of patients in the CURE trial during the initial hospitalization, the study provides convincing evidence that clopidogrel is beneficial in patients who are managed medically in addition to those undergoing PCI.

Prasugrel has a more rapid onset of action and can achieve a greater level of platelet inhibition when compared to clopidogrel. It can be a useful alternative to clopidogrel considering that approximately 20% to 25% of the population may be resistant to clopidogrel.¹⁰³ The use of prasugrel is not recommended for "upfront" therapy in patients with NSTEMI undergoing PCI due to an increase in bleeding complications without a significant reduction in composite endpoints.¹⁰⁴

Ticagrelor, a small molecule that binds reversibly to the P2Y₁₂ platelet receptor, exhibited greater efficacy than clopidogrel in the PLATO trial.¹⁰⁵ Major bleeding events did not differ between the groups, although bleeding not related to coronary-artery bypass

TABLE 78-6 Recommendations for the Use of Medications in NSTEMI/UA

| THERAPY | COR | LOE |
|--|-----|-----|
| OXYGEN | | |
| Oxygen only if SpO ₂ < 90% or respiratory distress | I | C |
| NITRATES | | |
| Sublingual nitroglycerin | I | C |
| IV nitroglycerin for persistent ischemia, HF, or hypertension | I | B |
| Nitrates are contraindicated if phosphodiesterase was recently used | III | B |
| ANALGESICS | | |
| Morphine sulfate for ongoing ischemic pain despite maximal medical therapy | IIb | B |
| NSAIDs (except aspirin) should not be initiated or should be discontinued | III | B |
| BETA BLOCKERS | | |
| Oral β -blockers should be initiated within the first 24 hours, in the absence of contraindications* | I | A |
| Use of metoprolol succinate, carvedilol, or bisoprolol is recommended in patients with NSTEMI and reduced systolic function with stabilized heart failure | I | C |
| IV β -blockers are contraindicated in patients with risk factors for or evidence of shock | III | B |
| STATIN THERAPY | | |
| Initiate or continue high-intensity statin therapy [†] in patients with no contraindications | I | A |
| Obtain a fasting lipid profile | IIa | C |
| RENIN ANGIOTENSIN ALDOSTERONE INHIBITORS | | |
| ACE inhibitors should be started and continued indefinitely in all patients with an LVEF < 40% and those with HTN, DM, or stable CKD unless contraindicated | I | A |
| ARBs should be given to ACE-I intolerant patients with an LVEF < 40% | I | A |
| Aldosterone blockade is recommended in patients post MI without significant renal dysfunction (Cr > 2.5 mg/dL in men or > 2.0 mg/dL in women) or hyperkalemia (K > 5.0 mEq/L) who are and have an LVEF < 40%, diabetes mellitus, or HF who are receiving therapeutic doses of ACE-I and β -blocker | I | A |

*Decompensated heart failure, low-output state, risk for cardiogenic shock, bradycardia, evidence of AV nodal conduction disease.

[†]Atorvastatin or rosuvastatin.

grafting occurred more often with ticagrelor. Ticagrelor has a faster onset of action when compared to clopidogrel and has a faster recovery of platelet function. Patients with NSTEMI in PLATO trial comparing clopidogrel to ticagrelor showed a reduction in the composite outcome of death from vascular causes, MI, or stroke (reduction: 11.7%-9.8%; HR: 0.84; $P < 0.001$) in patients treated with ticagrelor.¹⁰⁵ Table 78-7 summarizes the dosing of clopidogrel, prasugrel, and ticagrelor in the treatment of NSTEMI/UA.

Anticoagulant Therapy

Heparin is an important component of primary therapy for patients with unstable coronary syndromes without ST elevation. When added to aspirin, heparin has been shown to reduce refractory angina and the development of MI,³² and a meta-analysis of the available data indicates that the addition of heparin reduces the composite endpoint of death or MI.¹⁰⁶

Unfractionated heparin, however, can be difficult to administer, because the anticoagulant effect is unpredictable in individual patients. Therefore, the APTT (activated partial thromboplastin time) must be monitored closely. The potential for heparin-associated thrombocyto-

TABLE 78-7 Dosing of Clopidogrel, Prasugrel, and Ticagrelor in Patients with NSTEMI

| DRUG | LOADING DOSE | MAINTENANCE DOSE |
|-------------------------|------------------|------------------|
| Clopidogrel | 300 mg or 600 mg | 75 mg |
| Prasugrel [†] | Not recommended* | 10 mg |
| Ticagrelor [‡] | 180 mg | 90 mg BID |

Adapted from Amsterdam EA, Wenger NK, Brindis RG, Casey DE, Ganiats TG, Holmes DR, et al. 2014 AHA/ACC Guidelines for the Management of Patients With Non-ST-Elevation Acute Coronary Syndromes: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014; 130:e344-e426.

*Due to a significant increase in spontaneous bleeding, life-threatening bleeding, and fatal bleeding in the patients loaded with prasugrel compared with patients loaded with clopidogrel.

[†]Net harm in patients with a history of cerebrovascular events and no clinical benefit in patients older than 75 years of age or those with low body weight (<60 kg) (Wiviott SD, Braunwald E, McCabe CH, Montalescot G, Ruzyllo W, Gottlieb S, et al. Prasugrel versus clopidogrel in patients with acute coronary syndromes. *N Engl J Med*. 2007;357:2001-2015.)

[‡]The recommended maintenance dose of aspirin to be used with ticagrelor is 81 mg daily.

penia is also a safety concern. The recommended regimen is weight based and adjusted using a standardized nomogram.

Low-molecular-weight heparins (LMWHs) have several advantages. Since they bind less avidly to heparin-binding proteins, there is less variability in the anticoagulant response and a more predictable dose-response curve, obviating the need to monitor APTT. The incidence of thrombocytopenia is lower (but not absent, and patients with heparin-induced thrombocytopenia with antiheparin antibodies cannot be switched to LMWH). LMWH is less susceptible to inactivation by platelet factor 4. Finally, LMWHs have longer half-lives and can be given by subcutaneous injection.

Several trials have documented beneficial effects of LMWH therapy in unstable coronary syndromes.^{107,108} Specific considerations with the use of LMWH include a decreased clearance in renal insufficiency and the lack of a commercially available test to measure the anticoagulant effect. Enoxaparin is dosed by weight and in the presence of impaired renal function (CrCl < 30 mL/min) the dose should be reduced.

Direct Thrombin Inhibitors

Bivalirudin is a direct thrombin inhibitor (DTI). As opposed to heparin, bivalirudin binds directly to both circulating and clot-bound thrombin and inhibits the conversion of fibrinogen to fibrin in the final step of the clotting cascade. Direct thrombin inhibitors have several theoretic advantages over heparin. Heparin binds to a number of tissue and plasma proteins, which alters its bioavailability and clearance. Heparin may also have a platelet-activating effect in ACS. Last, DTIs do not bind to platelet factor 4 and therefore avoid the problem of heparin-induced thrombocytopenia.

Bivalirudin is the only DTI indicated for use in ACS. Bivalirudin appears to be equivalent to glycoprotein IIb/IIIa inhibitors plus heparin but with a lower bleeding rate.¹⁰⁹ However, patients who get bivalirudin alone without a thienopyridine prior to angiography or PCI may have a higher rate of composite ischemic events than patients who received heparin plus a glycoprotein IIb/IIIa inhibitor (9.1% vs. 7.1%).¹¹⁰ Therefore, it is not recommended that bivalirudin be administered alone, particularly if there is a going to be a delay to angiography.

Glycoprotein IIb/IIIa Antagonists

Given the central role of platelet activation and aggregation in the pathophysiology of unstable coronary syndromes, attention has been focused on platelet glycoprotein IIb/IIIa antagonists, which inhibit the final common pathway of platelet aggregation. Meta-analyses have found a relative risk reduction of 11% in NSTEMI.⁵² Additional analysis suggests that glycoprotein IIb/IIIa inhibition is most effective in high-risk patients, those with either EKG changes or elevated troponin.^{52,111}

The benefits appear to be restricted to patients undergoing percutaneous intervention, which may not be entirely surprising.

The studies mentioned above were conducted prior to the era of dual antiplatelet therapy. As mentioned previously, it is common practice to administer a P2Y₁₂ inhibitor and aspirin in conjunction with an anticoagulant in patients with ACS. For patients with UA/NSTEMI undergoing an initial invasive approach, the most recent data suggest that either a glycoprotein IIb/IIIa inhibitor or P2Y₁₂ inhibitors can be given in addition to aspirin and an anticoagulant if the patient is considered low risk (troponin negative). However, if the patient is considered high risk (troponin positive, recurrent ischemic features) both a glycoprotein IIb/IIIa inhibitor and clopidogrel can be given in addition to aspirin and an anticoagulant.⁵⁵ In patients with intermediate/high-risk features (e.g., positive troponin) treated with an early invasive strategy, a GP IIb/IIIa inhibitor may be considered, with tirofiban and eptifibatide preferred.⁹⁵

Complications of Acute Myocardial Infarction

Ventricular Free Wall Rupture

Ventricular free wall rupture typically occurs during the first 5 days after an infarction and within 2 weeks in over 90% of cases. The incidence of LV free wall rupture in all comers with STEMI is low (about 1%). Not surprisingly, the incidence in those who die following STEMI is much higher, ranging from 7% to 26%.¹¹²⁻¹¹⁴ The classic patient is elderly, female, and status postanterior wall infarction. Early use of fibrinolytic therapy reduces the incidence of cardiac rupture, but late use may actually increase the risk. Pseudoaneurysm with leakage may be heralded by chest pain, nausea, and restlessness, but frank free wall rupture presents as a catastrophic event with shock and electromechanical dissociation. Pericardiocentesis may be necessary to relieve acute tamponade, ideally in the operating room since the pericardial effusion may tamponade the bleeding. Salvage is possible with expeditious thoracotomy and repair, either with a patch or by direct suturing.¹¹⁵ For those patients who make it to the operating room for repair, mortality approaches 60%.⁶

Ventricular Septal Rupture

Septal rupture presents as severe heart failure or cardiogenic shock, with a loud pansystolic murmur and parasternal thrill. Ventricular septal rupture most commonly occurs within 24 hours of reperfusion in patients with a STEMI.¹¹⁶ The hallmark finding is a left-to-right intracardiac shunt ("step up" in oxygen saturation from the right atrium to right ventricle), but the diagnosis is most easily made with echocardiography. Rapid institution of supportive pharmacologic measures and mechanical support, such as intraaortic balloon pumping is necessary. Operative repair is the only viable option for long-term survival. Even if surgical repair is done promptly, mortality remains high, ranging from 20% to 87%.¹¹⁶⁻¹¹⁹

Acute Mitral Regurgitation

Ischemic mitral regurgitation is usually associated with inferior myocardial infarction and ischemia or infarction of the posterior papillary muscle, although an anterior papillary muscle rupture can also occur. Papillary muscle rupture has a bimodal incidence, either within 24 hours or 3 to 7 days after an acute myocardial infarction. It presents dramatically with pulmonary edema, hypotension, and cardiogenic shock. When a papillary muscle ruptures, the murmur of acute mitral regurgitation may be limited to early systole because of a rapid equalization of pressures in the left atrium and ventricle. More important, the murmur may be soft or inaudible, especially when the cardiac output is low.¹²⁰

Echocardiography is extremely useful in the differential diagnosis, which includes free wall rupture, ventricular septal rupture, and infarct extension with pump failure. Hemodynamic monitoring with pulmonary artery catheterization may also be helpful. Management includes an afterload reduction with an intraaortic balloon pumping as a temporizing measure. Inotropic or vasopressor therapy may also be needed

to support cardiac output and blood pressure. Definitive therapy, however, is a surgical valve repair or replacement, which should be undertaken as soon as possible since clinical deterioration can be sudden.^{120,121}

RIGHT VENTRICULAR INFARCTION

Right ventricular infarction occurs in up to 30% of patients with an inferior infarction and is clinically significant in 10%.¹²² The combination of a clear chest x-ray with jugular venous distention in a patient with an inferior wall MI should lead to the suspicion of a coexisting right ventricular infarct. The diagnosis is substantiated by a demonstration of ST-segment elevation in the right precordial leads (V_{3R} to V_{5R}) or by characteristic hemodynamic findings on the right heart catheterization (elevated right atrial and right ventricular end-diastolic pressures with normal to low pulmonary artery occlusion pressure and low cardiac output). Echocardiography can demonstrate a depressed right ventricular contractility.¹²³ Patients with cardiogenic shock on the basis of right ventricular infarction have a better prognosis than those with left-sided pump failure.¹²¹ This may be due in part to the fact that the right ventricular function tends to return to normal over time with supportive therapy, although such therapy may need to be prolonged.¹²⁴

In patients with right ventricular infarction, right ventricular preload should be maintained with fluid administration. In some cases, however, fluid resuscitation may increase pulmonary capillary occlusion pressure but may not increase cardiac output, and overdistention of the right ventricle can compromise left ventricular filling and cardiac output.¹²⁴ Inotropic therapy may be more effective in increasing cardiac output in some patients, and monitoring with serial echocardiograms may also be useful to detect a right ventricular overdistention. Maintenance of atrioventricular synchrony is also important in these patients to optimize right ventricular filling.¹²³ For patients with continued hemodynamic instability, intraaortic balloon pumping may be useful, particularly because elevated right ventricular pressures and volumes increase wall stress and oxygen consumption and decrease right coronary perfusion pressure, exacerbating right ventricular ischemia. Reperfusion of the occluded coronary artery is also crucial.¹²⁵

CARDIOGENIC SHOCK

Epidemiology and Pathophysiology

Cardiogenic shock, resulting either from left ventricular pump failure or mechanical complications, represents the leading cause of in-hospital death after myocardial infarction.^{126,127} Cardiogenic shock should be considered in the presence of persistent hypotension (systolic blood pressure <90 mm Hg or mean arterial pressure 30 mm Hg lower than baseline) with reduced cardiac index (<1.8 L/min/m² without support or <2.2 L/min/m² with support) and adequate or elevated filling pressures.¹²⁸ Patients may have cardiogenic shock at initial presentation, but shock most often evolves over several hours.^{129,130}

Cardiac dysfunction in patients with cardiogenic shock is usually initiated by a myocardial infarction or ischemia. The myocardial dysfunction resulting from ischemia worsens the ischemia, creating a downward spiral (Fig. 78-4). Compensatory mechanisms that retain fluid in an attempt to maintain cardiac output may add to the vicious cycle and further increase diastolic filling pressures. The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock. Early recognition of cardiogenic shock and timely management (revascularization) are paramount to improved mortality.

Initial Management

Maintenance of adequate oxygenation and ventilation is critical. Many patients require intubation and mechanical ventilation if only to reduce the work of breathing and facilitate sedation and stabilization before cardiac catheterization. Electrolyte abnormalities should be corrected,

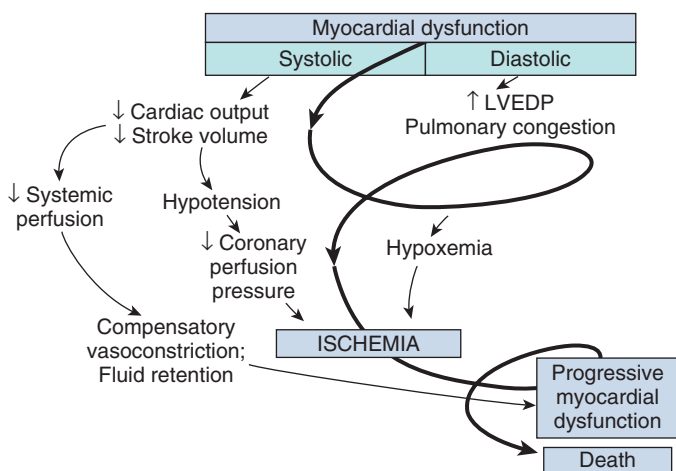

FIGURE 78-4 ■ The “downward spiral” in cardiogenic shock.

Stroke volume and cardiac output fall with left ventricular (LV) dysfunction, producing hypotension and tachycardia that reduce coronary blood flow. Increasing ventricular diastolic pressure reduces coronary blood flow, and increased wall stress elevates the myocardial oxygen requirements. All of these factors combine to worsen ischemia. The falling cardiac output also compromises systemic perfusion. Compensatory mechanisms include sympathetic stimulation and fluid retention to increase preload. These mechanisms can actually worsen cardiogenic shock by increasing myocardial oxygen demand and afterload. Thus, a vicious circle can be established. LVEDP, left ventricular end-diastolic pressure. (Adapted with permission from Hollenberg SM, Kavinsky CJ, Parrillo JE. Cardiogenic shock. *Ann Intern Med* 1999;131:47–59.)

and morphine (or fentanyl if systolic pressure is compromised) used to relieve pain and anxiety. Arrhythmias and a heart block may have important effects on cardiac output and should be corrected promptly with antiarrhythmic drugs, cardioversion, or pacing. Amiodarone is the preferred antiarrhythmic drug for sustained ventricular or atrial tachyarrhythmias in the setting of cardiogenic shock.

Both pharmacologic and mechanical forms of circulatory support should be used to reverse hypotension and maintain organ and coronary artery perfusion. Patients are commonly diaphoretic, and relative hypovolemia may be present in as many as 20% of patients with cardiogenic shock, so fluid boluses, titrated to clinical endpoints of heart rate, urine output, and blood pressure, should be considered as an initial measure unless frank pulmonary edema is present. Patients who do not respond rapidly to initial fluid boluses or those with poor physiologic reserves should be considered for invasive hemodynamic monitoring. Optimal filling pressures vary from patient to patient; hemodynamic monitoring can be used to construct a Starling curve at the bedside, identifying the filling pressure at which the cardiac output is maximized. Maintenance of an adequate preload is particularly important in patients with a right ventricular infarction.

Vasopressor and inotropic agents remain the mainstay of first-line therapy in the management of cardiogenic shock. Catecholamine agents, such as norepinephrine, epinephrine, dopamine, dobutamine, and phenylephrine, have both vasopressor and inotropic effects, but it is useful to distinguish vasopressor effects (those aimed at maintaining blood pressure) and inotropic effects (those aimed at increasing myocardial contractility and thus cardiac output) to allow for a titration of dose to effect. When the arterial pressure remains inadequate, therapy with vasopressor agents may be required to maintain coronary perfusion pressure, to break the vicious cycle of progressive hypotension with further myocardial ischemia. The most commonly used vasopressors include norepinephrine, phenylephrine, and epinephrine. Norepinephrine acts on both alpha-1 and beta-1 adrenergic receptors, thus producing potent vasoconstriction, as well as a modest increase in

cardiac output,¹³¹ and is the preferred first-line agent. A subgroup analysis of a multicenter randomized trial comparing norepinephrine to dopamine in patients with shock demonstrated a lower 28-day mortality with norepinephrine ($P = 0.03$).¹³² Phenylephrine, a selective alpha-1 adrenergic agonist, acts as a potent vasoconstrictor that augments systemic vascular resistance (SVR) without greatly affecting contractility or CO. Phenylephrine may be used when tachyarrhythmias limit therapy with other vasopressors. Epinephrine has a potent beta-1 adrenergic receptor activity and moderate beta-2 and alpha-1 adrenergic receptor effects. The net effect can be an increase in cardiac output and decreased systemic vascular resistance (SVR), with escalating doses causing a greater increase in SVR. Epinephrine is typically used in addition to norepinephrine in septic shock, and for the management of hypotension following coronary artery bypass grafting.

Vasopressor infusions need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Hemodynamic monitoring, with serial measurements of cardiac output and filling pressures (and other parameters, such as mixed venous oxygen saturation) can allow for titration of the dosage of vasoactive agents to the minimum dosage required to achieve the chosen therapeutic goals.¹³³ However, reperfusion therapy should not be delayed for the placement of a pulmonary artery catheter.

Following the initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed. If tissue perfusion is adequate but significant pulmonary congestion remains, diuretics may be employed. Vasodilators can be considered as well, depending on the blood pressure.

If tissue perfusion remains inadequate, cardiovascular support with inotropic agents should be initiated. There is no firm guideline-based recommendation regarding which inotropic agent to use in the setting of cardiogenic shock. Typically used inotropes include dobutamine, dopamine, and norepinephrine (which can act as both a vasopressor and inotrope). Dobutamine, a selective β_1 -adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output. Dobutamine may exacerbate hypotension in some patients and can precipitate tachyarrhythmia. Dobutamine is typically reserved for patients with an SBP over 80 mm Hg. Epinephrine can increase cardiac output but often at the expense of a substantial increase in myocardial oxygen demand. In some situations, a combination of a vasopressor and an inotrope can be more effective than either agent used alone. Phosphodiesterase inhibitors such as milrinone are less arrhythmogenic than catecholamines, but have the potential to cause hypotension, and should be used with caution in patients with tenuous clinical status.

Mechanical Support in Cardiogenic Shock

Intraaortic balloon counterpulsation (IABP) reduces the systolic afterload and augments diastolic perfusion pressure, increasing cardiac output and improving coronary blood flow.¹³⁴ These beneficial effects, in contrast to those of inotropic or vasopressor agents, occur without an increase in oxygen demand. IABP does not, however, produce a significant improvement in blood flow distal to a critical coronary stenosis.^{134,135} The timing and utility of IABP in patients with STEMI complicated by cardiogenic shock, however, remain uncertain.^{136,137} The IABP-SHOCK II trial, a multicenter, randomized open-label multicenter trial, allocated 600 patients with cardiogenic shock complicated by acute MI to either IABP or no IABP at the time of PCI. There was no difference in all-cause mortality at 30 days (39.7% vs. 41.3%, $P = 0.69$) or 12 months (52% vs. 51%), nor was there any significant difference in any of the subgroups.¹³⁸ Some randomized patients in this trial received an IABP after PCI when they were hemodynamically stable and might not have been expected to derive great benefit. In addition, 10% of patients in the control group crossed over to IABP therapy. IABP is widely available, is easy to place, and has a lower cost compared to other support devices; as such, IABP may still have a role in the stabilization of selected patients with cardiogenic shock.

In appropriate settings, more intensive support with mechanical assist devices may also be implemented. Such devices include left ventricular and biventricular assist devices, percutaneous left atrial-to-femoral arterial ventricular assist device (Tandem Heart™), percutaneous transvalvular left ventricular assist device (Impella™), and percutaneous cardiopulmonary bypass support with the use of an extracorporeal membrane oxygenator (ECMO). The percutaneous LVADs provide better hemodynamics compared with IABP, with higher cardiac indices and mean arterial pressures, as well as lower filling pressures, and improve metabolic parameters. However, there is conflicting evidence regarding mortality.^{139,140}

Reperfusion Therapy

Although fibrinolytic therapy reduces the likelihood of the subsequent development of shock after the initial presentation, it is clearly less effective in patients with cardiogenic shock than in those without¹⁴¹ and has not been shown to reduce mortality in patients with established cardiogenic shock.^{13,142}

To date, emergency percutaneous revascularization is the only intervention that has been shown to reduce mortality rates consistently in patients with cardiogenic shock. An extensive body of observational and registry studies has shown consistent benefits from revascularization.^{143,144} These data have been confirmed in the SHOCK study, a randomized, multicenter international trial that assigned patients with cardiogenic shock to receive optimal medical management (including IABP and fibrinolytic therapy) or to cardiac catheterization with revascularization using PTCA or CABG.^{21,145} The trial enrolled 302 patients and was powered to detect a 20% absolute decrease in 30-day all-cause mortality rates. Mortality at 30 days was 46.7% in patients treated with early intervention and 56% in patients treated with initial medical stabilization, but this difference did not quite reach statistical significance ($P = 0.11$).²¹ At 6 months, the absolute risk reduction with early invasive therapy in the SHOCK trial was 13% (50.3% compared with 63.1%, $P = 0.027$), and this risk reduction was maintained at 12 months (mortality 53.3% vs. 66.4%, $P < 0.03$).¹⁴⁵ The subgroup analysis showed a substantial improvement in mortality rates in patients younger than 75 years of age at both 30 days (41.4% vs. 56.8%, $P = 0.01$) and 6 months (44.9% vs. 65.0%, $P = 0.003$).¹⁴⁵ Put into perspective with the results from other randomized, controlled trials of patients with acute myocardial infarction, an important point emerges: despite the moderate relative risk reduction (0.72, CI 0.54-0.95) the absolute benefit is important, with 9 lives saved for 100 patients treated at 30 days (number needed to treat, 10.8), and 13.2 lives saved for 100 patients treated at 1 year in the SHOCK trial (number needed to treat 7.6). Based on these data trials, the presence of cardiogenic shock in the setting of acute MI is an indication for emergency revascularization, either by percutaneous intervention or CABG.⁶

See Table 78-8 for a summary of complications due to acute myocardial infarction.

TABLE 78-8 Complications Due to Acute Myocardial Infarction

| |
|---|
| Cardiogenic shock |
| Mechanical |
| Rupture of the left ventricular free wall |
| Rupture of the interventricular septum |
| Acute mitral regurgitation |
| Left ventricular aneurysm |
| Ventricular arrhythmia |
| Bradycardia or AV nodal block |
| Pericarditis |
| Bleeding |

KEY POINTS

1. The definition of myocardial infarction (MI) has evolved. Now, the patient's clinical presentation is considered in conjunction with highly sensitive and specific serum markers, the electrocardiogram (ECG), advanced imaging techniques, and pathologic samples.
2. Atypical presentations of acute myocardial infarction (AMI) are seen in up to 30% of infarct patients. The rate of atypical presentation is highest among the very elderly in whom mental status change, syncope, and other nonspecific symptom/sign complexes are seen. Atypical presentations are more likely to be encountered in the ill critical care patient.
3. The ECG is diagnostic (i.e., ST segment elevation or new left bundle branch block [LBBB]) for AMI in only 50% of patients ultimately diagnosed with an acute infarction. The remainder of these AMI patients demonstrate normal, nonspecifically abnormal, abnormal but not diagnostic, and confounding patterns.
4. Cardiac troponin is the diagnostic marker of choice. While highly specific, serial measurements should be obtained to identify MI properly.
5. Echocardiography (ECHO) is a valuable noninvasive tool. It can be utilized under many clinical circumstances to help identify MI and its complications.

ANNOTATED REFERENCES

Thygesen K, Alpert JS, White HD, on behalf of the Joint ESC/ACCF/AHA/WHF Task Force for the Redefinition of Myocardial Infarction. Universal definition of myocardial infarction. *Circulation* 2007;116:2634-2653.

This article is vital to the understanding of MI. Not only is myocardial infarction defined, but the subtypes of AMI encountered in the critical care environment are also delineated. The "typical rise and fall" description of the serum marker pattern encountered in AMI is discussed; this portion of the paper is vital to understanding AMI and differentiating MI-related troponin elevations from noninfarction serum marker abnormalities.

Hoekstra JW, O'Neill BJ, Pride YB, et al. Acute detection of ST-elevation myocardial infarction missed on standard 12-lead ECG with a novel 80-lead real-time digital body surface map: primary results from the multicenter OCCULT MI trial. *Ann Emerg Med* 2009;54:779-788.

This paper investigates the use of the additional ECG lead concept taken to extreme: the use of ECG body mapping. In the discussion, the authors note that the traditional 12-lead ECG can and does "miss" some ACS events, including STEMI. They found that the ECG body map provided an incremental increase in STEMI detection as compared to the 12-lead; in fact, an increase in STEMI diagnosis by 28% was reported. Importantly, in patients with an ECG body map, only STEMI have adverse outcomes similar to those of 12-lead STEMI patients, yet these patients are managed much less aggressively in the early phase of presentation.

Lim W, Whitlock R, Khara V, et al. Etiology of troponin elevation in critically ill patients. *J Crit Care* 2010;25:322-328.

A small but interesting study exploring the etiology of elevated troponin values in the ICU patient. These investigators found that approximately half of the ICU patients with elevated troponin values experienced AMI; sepsis and renal failure accounted for the next most frequently encountered cause of elevated troponin.

Body R. Emergent diagnosis of acute coronary syndromes: today's challenges and tomorrow's possibilities. *Resuscitation* 2008;78:13-20.

This article nicely summarizes the pros and cons of the various diagnostic studies and diagnostic strategies in the evaluation of patients suspected of AMI.

Goodacre S, Pett P, Arnold J, et al. Clinical diagnosis of acute coronary syndrome in patients with chest pain and a normal or nondiagnostic electrocardiogram. *Emerg Med J* 2009;26:866-870.

This paper investigates the patient with a nondiagnostic ECG who is ultimately diagnosed with ACS. It importantly makes the point that the ECG is a fallible study, and when the clinical situation suggests the diagnosis, ACS cannot be excluded based upon a normal or nondiagnostic ECG.

■ CLASSIFICATION AND EPIDEMIOLOGY

Supraventricular arrhythmias include rhythms arising from the sinus node and the adjacent atrial tissue (inappropriate sinus tachycardia, sinoatrial reentry tachycardia), both the right and left atria (atrial tachycardia, flutter, and fibrillation), the atrioventricular (AV) node (AV nodal reentry tachycardia, accelerated ectopic junctional rhythm), and the AV node, with involvement of an accessory pathway or multiple pathways (AV reentry tachycardia) (Fig. 79-1).

Atrioventricular Nodal Reentry Tachycardia and Atrioventricular Reentry Tachycardia

AV nodal reentry tachycardia and AV reentry tachycardia are usually referred to as *paroxysmal supraventricular tachycardias*. They are often seen in young patients with little or no structural heart disease, although a congenital heart abnormality giving rise to increased atrial pressure and dilatation (e.g., Ebstein's anomaly, atrial septal defect, Fallot's tetralogy) can coexist in a small percentage of patients with these arrhythmias.¹ The first presentation is common between age 12 and 30 years, and the prevalence is approximately 2.5 per 1000. Women are twice as likely as men to present with AV nodal reentry tachycardia.

Atrial Flutter and Fibrillation

Atrial fibrillation is the most common supraventricular arrhythmia, affecting 1% to 2% of the general population, especially the elderly. It is usually associated with cardiovascular pathologies, among which hypertension and congestive heart failure prevail.² About a third of patients, however, present with no underlying heart disease and are considered to have "lone" atrial fibrillation. The incidence of isolated atrial flutter is largely unknown and is believed to be in the range of 0.037% to 0.88% per 1000 person-years, but at least half of these patients also have atrial fibrillation as a coexistent arrhythmia.

Atrial Tachycardia

Atrial tachycardia affects 0.34% to 0.46% of patients with arrhythmias. It is common in younger individuals following surgical correction of congenital heart disease and in the elderly, in whom it often occurs in association with atrial fibrillation.

Other Supraventricular Tachycardias

Inappropriate sinus tachycardia and sinoatrial reentry tachycardia are less well-defined clinical and electrocardiographic entities, and their prevalence and associated conditions are not well characterized. Sinoatrial reentry tachycardia is found incidentally in 1.8% to 16.9% of patients undergoing electrophysiologic studies for other supraventricular tachyarrhythmias.

■ CLINICAL PRESENTATION

The leading symptom of most supraventricular tachyarrhythmias, particularly AV nodal reentry tachycardia and AV reentry tachycardia, is rapid, regular palpitations, usually with an abrupt onset; they can

occur spontaneously or be precipitated by simple movements. A common feature of tachycardias that involve circulation through the AV node is termination by the Valsalva maneuver. In younger individuals with no structural heart disease, the rapid heart rate can be the main pathologic finding. Other symptoms may include anxiety, dizziness, dyspnea, neck pulsation, central chest pain, weakness, and occasionally polyuria due to the release of atrial natriuretic peptide in response to increased atrial pressures (more common in atrial tachycardia and AV nodal reentry tachycardia). Prominent jugular venous pulsations due to atrial contractions against closed AV valves may be observed during AV nodal reentry or AV reentry tachycardia.

True syncope is relatively uncommon unless uncontrolled tachycardia over 200 beats per minute is sustained for a long period, especially in patients who remain standing. Syncope has been reported in 10% to 15% of patients, usually just after onset of the arrhythmia or in association with a prolonged pause following its termination. However, in older patients with concomitant heart disease such as aortic stenosis, hypertrophic cardiomyopathy, and cerebrovascular disease, significant hypotension and syncope may result from profound hemodynamic collapse associated with only moderately fast ventricular rates.

It is essential to recognize that patients presenting with AV reentry tachycardia may also present with atrial fibrillation. If an accessory pathway has a short antegrade effective refractory period (<250 msec), it may conduct impulses to the ventricles at an extremely high rate and cause ventricular fibrillation. The incidence of sudden death is 0.15% to 0.39% per patient-year, and this may be the first manifestation of the disease in younger individuals.

Irregular palpitations may be due to atrial premature beats, atrial flutter with varying AV conduction block, atrial fibrillation, or multifocal atrial tachycardia. Although highly symptomatic, these arrhythmias usually have a benign hemodynamic prognosis. However, in patients with depressed ventricular function, uncontrolled atrial fibrillation can reduce cardiac output and precipitate hypotension and congestive heart failure. Atrial fibrillation in association with slow AV conduction or complete block (Frederick's syndrome) may result in hemodynamic collapse. Inappropriate sinus tachycardia and nonparoxysmal accelerated junctional rhythm are characterized by relatively slow heart rates and gradual onset and termination.

■ ELECTROCARDIOGRAPHY

Whenever possible, a 12-lead electrocardiogram (ECG) should be taken during the tachycardia. If a patient with an arrhythmia is hemodynamically unstable, a monitor strip should be obtained from the defibrillator before electrical discharge.

Narrow-Complex Tachycardias

The typical ECG feature is narrow QRS complexes less than 120 msec. In this case, the tachycardia is almost always supraventricular, and the differential diagnosis relates to its mechanism (Fig. 79-2).

Wide-Complex Tachycardias

The differential diagnostic features of wide-complex tachycardias favoring a supraventricular origin of the arrhythmia include, but are not limited to, preexistent bundle branch block; rate-dependent

aberrancy; antidromic AV reentry tachycardia, when an accessory pathway conducts and excites the ventricles antegradely; and prominent electrolyte abnormalities (e.g., hypokalemia) or heart muscle disease (cardiomyopathy), all of which may result in QRS widening (Fig. 79-3). If the diagnosis of supraventricular tachycardia cannot be proved, the patient should be treated as if ventricular tachycardia is present. Immediate direct current (DC) cardioversion is the treatment for any hemodynamically unstable tachycardia.

FIGURE 79-1 ■ Supraventricular tachyarrhythmias encountered in the emergency setting. AV, atrioventricular.

ATRIOVENTRICULAR NODAL REENTRY TACHYCARDIA

Mechanism

In AV nodal reentry tachycardia, there are two functionally and anatomically different pathways within the AV node: one is characterized by a short effective refractory period and slow conduction, and the other has a longer effective refractory period and faster conduction. In sinus rhythm, the atrial impulse that depolarizes the ventricles usually conducts through the fast pathway. If the atrial impulse (e.g., an atrial premature beat) occurs early, when the fast pathway is still refractory, the slow pathway takes over in propagating the atrial impulse to the ventricles; the impulse then travels back through the fast pathway, which by then has recovered its excitability, thus initiating the most common “slow-fast,” or typical, AV nodal reentry tachycardia.

Electrocardiographic Presentation

In sinus rhythm, the ECG is usually normal unless other unrelated abnormalities are present. During AV nodal reentry tachycardia, the rhythm is regular, with narrow QRS complexes and a rate of 140 to 250 beats per minute. The atria are activated retrogradely, producing inverted P waves in leads II, III, and aVF. Because atrial and ventricular depolarization occur simultaneously, the P waves are often obscured by the QRS complexes and cannot be detected on the surface ECG (Fig. 79-4, A). However, in about one third of cases of slow-fast AV nodal reentry tachycardia, a terminal positive deflection may be present in lead aVR or V₁ (or both), imitating right bundle branch block, or pseudo-S waves may be noted in the inferiorly oriented leads; these findings reflect retrograde activation of the atria. Tachycardia using these pathways in reverse (“fast-slow,” or long RP, tachycardia) is less common, occurring in 5% to 10% of cases.

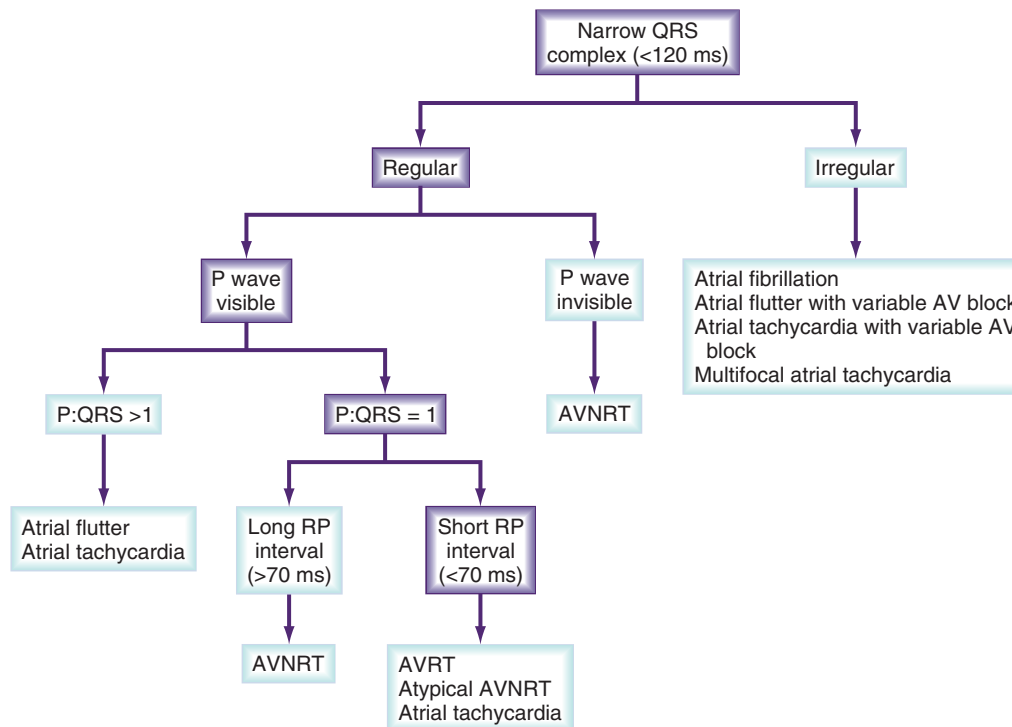

FIGURE 79-2 ■ Differential diagnosis for narrow QRS complex (presumably supraventricular) tachycardias. Note that ventricular tachycardia may present with narrow QRS complexes (e.g., fascicular tachycardia). AV, atrioventricular; AVNRT, atrioventricular nodal reentry tachycardia; AVRT, atrioventricular reentry tachycardia.

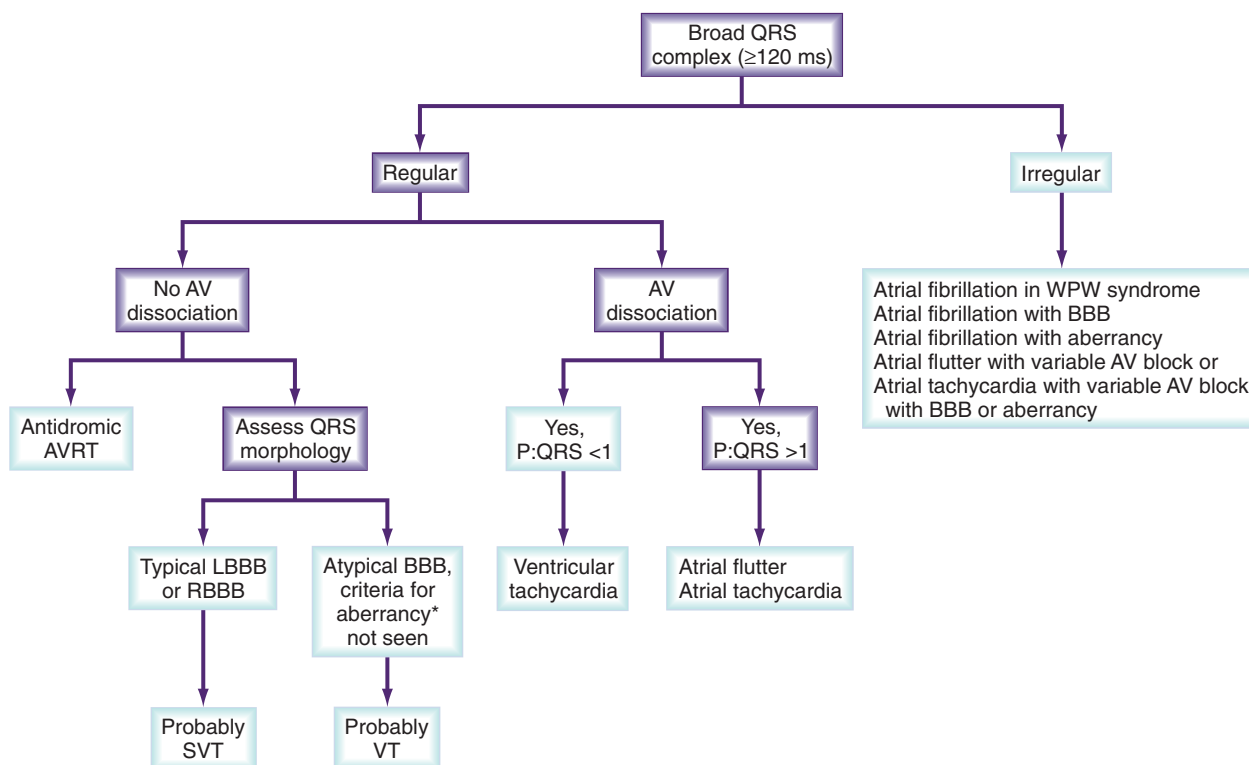

FIGURE 79-3 ■ Differential diagnosis for wide QRS complex tachycardias. AV, atrioventricular; AVRT, atrioventricular reentry tachycardia; BBB, bundle branch block; LBBB, left bundle branch block; RBBB, right bundle branch block; SVT, supraventricular tachycardia; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White. *Criteria for aberrancy: rate dependency, triphasic QRS complexes, rSR in V_1 with R >, QRS width <140 msec, QRS deflections are discordant in precordial leads, absence of fusion complexes and capture beats.

FIGURE 79-4 ■ **A**, Atrioventricular nodal reentry tachycardia, slow-fast type. Note narrow QRS complexes and absence of P waves. **B**, Atrioventricular reentry orthodromic tachycardia. Retrograde inverted P waves follow QRS complexes in leads II, III, and aVF. **C**, Atrioventricular reentry antidromic tachycardia with wide QRS complexes. Electrocardiogram during sinus rhythm with a QRS complex morphology identical to that seen during tachycardia may be helpful in the diagnosis. **D**, Atrial fibrillation in preexcitation syndrome with a fast ventricular rate response.

ATRIOVENTRICULAR REENTRY TACHYCARDIA

Accessory Pathways

AV reentry tachycardia occurs as a result of an anatomically distinct AV connection termed an *accessory pathway*, produced by incomplete separation of the atria and ventricles during fetal development. The most common AV accessory pathway (often called a *Kent bundle*) is located around the mitral or tricuspid annulus. In about 10% of cases, there are multiple pathways.

Accessory pathways are capable of conduction in either or both directions. Accessory pathways that are capable of antegrade conduction are referred to as *manifest*, demonstrating a delta wave during sinus rhythm when the atrial impulses conduct over the accessory pathway without encountering AV delay. The PR interval is short (<120 msec), and the QRS complex is wide; this occurs because the atrial impulse enters nonspecialized ventricular myocardium, and depolarization progresses slowly at first, giving rise to the delta wave before it is overtaken by a depolarization wavefront propagating via the normal conduction tissue. An accessory pathway that is capable of only retrograde conduction is termed *concealed* and does not produce a short PR interval or delta wave during sinus rhythm.

Mechanism and Electrocardiographic Presentation

The reentry circuit of orthodromic AV reentry tachycardia involves the AV node and an accessory pathway, with the impulses conducting from

the atria to the ventricles over the AV node and traveling in the reverse direction through the accessory pathway (see Fig. 79-4, B). In antidromic AV reentry tachycardia, the reentrant impulses conduct antegradely from the atria to the ventricles via an accessory pathway and retrogradely via the AV node or a second accessory pathway (see Fig. 79-4, C). Antidromic AV reentry tachycardia is uncommon (<10% of cases). Atrial fibrillation is usually encountered in patients with antegradely conducting pathways (see Fig. 79-4, D).

Acute Management

In an emergency, distinguishing between AV nodal reentry tachycardia and AV reentry tachycardia may be difficult, but it is usually not critical because both tachycardias respond to the same treatment. If the patient is hemodynamically stable, vagal maneuvers, including carotid sinus massage, the Valsalva maneuver, and facial immersion in cold water (diving reflex), can terminate tachycardia in about 50% of patients (Box 79-1).^{3,4} Commercially available gel packs can be used as cold compresses instead of facial immersion, but the most important elements are wet nostrils and breath-holding.

Pharmacologic Termination

AV blocking agents, such as adenosine, verapamil, diltiazem, and beta-blockers, are effective in terminating both AV nodal reentry and AV reentry tachycardia (Table 79-1).¹

Adenosine

Intravenous (IV) adenosine is effective in diagnosing, rate slowing, and often terminating narrow-complex tachycardias.⁵ Adenosine usually terminates AV nodal reentry tachycardia and AV reentry tachycardia but rarely interrupts the atrial flutter circuit and does not suppress automatic atrial tachycardia; it can, however, produce high-degree AV block during which the tachycardia persists (Fig. 79-5). It has no effect on most ventricular tachycardias. Adenosine is advantageous compared with verapamil because of its rapid onset and absence of a negative inotropic effect in patients with poor left ventricular function and those with significant hypotension.

Adenosine is administered as a very rapid 3- to 6-mg IV bolus; if this is ineffective, another 6- to 12-mg bolus can be given 2 to 5 minutes later. Adenosine is metabolized very quickly, with an effective half-life

of 10 seconds. Adverse effects, including dyspnea, facial flushing, and chest tightness, are therefore short-lived, but in about 12% of patients, adenosine may shorten the atrial effective refractory period and provoke atrial flutter or fibrillation or accelerate conduction over the accessory pathway and produce a rapid ventricular response. In a proportion of patients, ventricular premature beats and nonsustained ventricular tachycardia may occur after the successful termination of

BOX 79-1

Vagal Maneuvers to Terminate Tachycardia

CAROTID SINUS MASSAGE

Ensure that there is no significant carotid artery disease (carotid bruits).

Monitor the electrocardiogram continuously.

Place the patient in the supine position with the head slightly extended.

Start with right carotid sinus massage.

Apply firm rotatory or steady pressure to the carotid artery at the level of the third cervical vertebra for 5 sec.

If no response, massage the left carotid sinus.

Generally, right carotid sinus massage decreases sinus node discharge, and left carotid sinus massage slows atrioventricular conduction.

Do not massage both carotids at the same time.

A single application of carotid sinus pressure is effective in about 20% to 30% of patients with paroxysmal supraventricular tachycardias; multiple applications terminate tachycardia in about 50% of patients.

Asystole is a potential but rare complication.

VALSALVA MANEUVER

Valsalva maneuver involves an abrupt voluntary increase in intrathoracic and intraabdominal pressures by straining.

Monitor the electrocardiogram continuously.

Place the patient in the supine position.

The patient should not take a deep inspiration before straining.

Ideally, the patient blows into a mouthpiece of a manometer against a pressure of 30 to 40 mm Hg for 15 sec.

Alternatively, the patient strains for 15 sec while breath-holding.

Transient acceleration of tachycardia usually occurs during the strain phase as a result of sympathetic excess.

On release of strain, the rate of tachycardia slows because of the compensatory increase in vagal tone (baroreceptor reflex); it may terminate in about 50% of patients.

Termination of tachycardia may be followed by pauses and ventricular ectopics.

TABLE 79-1 Acute Pharmacologic Rate Control in Atrial Tachyarrhythmias

| DRUG | ROUTE OF ADMINISTRATION | DOSE | ONSET | POTENTIAL ADVERSE EFFECTS |
|-------------|-------------------------|--|-----------|--|
| Verapamil | Intravenous | 5-10 mg (0.075-0.15 mg/kg) over 2 min; if no response, additional 5-10 mg after 15-30 min; 3-10 mg every 4-6 h for rate control | 3-5 min | Hypotension, bradycardia, heart block, possible deterioration of ventricular function in the presence of organic heart disease |
| Diltiazem | Intravenous | 0.25 mg/kg over 2 min; if no response, additional 0.35 mg/kg after 15-30 min; followed by 5-15 mg/h infusion for rate control | 2-7 min | |
| Esmolol | Intravenous | 0.5 mg/kg over 1 min, followed by 0.05-0.2 mg/kg/min for 4 min; if no response after 5 min, 0.5 mg/kg for 1 min, followed by 0.1 mg/kg for 4 min; infusion 0.05-0.2 mg/kg/min for rate control | 2-3 min | Hypotension, bradycardia, heart block, possible deterioration of ventricular function in the presence of organic heart disease |
| Metoprolol | Intravenous | 2.5-5 mg over 2 min followed by repeat doses if necessary (total 10-15 mg) | 5 min | |
| Atenolol | Intravenous | 2.5 mg over 2 min, followed by repeat doses if necessary (total 10 mg) or infusion 0.15 mg/kg for 20 min | 5-10 min | |
| Propranolol | Intravenous | 1 mg over 1 min (total 10-12 mg; 0.15 mg/kg) | 5 min | |
| Digoxin | Intravenous | 0.5-1 mg, followed by 0.25 mg every 2-4 h (maximum, 1.5 mg) | 30-60 min | Bradycardia, atrioventricular block, atrial arrhythmias, ventricular tachycardia |

Intravenous amiodarone can also be effective for rate control, especially in patients with poor left ventricular function, but there is insufficient evidence to support this recommendation. The rate-slowing effect of amiodarone is usually delayed by 1-2 hours.

FIGURE 79-5 ■ **A**, Adenosine usually terminates atrioventricular reentry tachycardias. **B** and **C**, It rarely interrupts the atrial flutter circuit or suppresses automatic focal atrial tachycardia but produces high-degree atrioventricular block during which the tachycardia persists.

the supraventricular tachycardia.⁶ Some individuals, particularly heart transplant recipients, are unusually sensitive to adenosine and require a lower dose (1 mg).

Verapamil and Diltiazem

Verapamil is administered as a 5- to 10-mg IV bolus over 2 minutes, and the effect on the tachycardia should occur in 5 to 10 minutes. If necessary, a second bolus of 10 mg can be given 30 minutes after the initial dose. Vagal maneuvers can be effective at this stage. Verapamil should not be used for wide-complex tachycardias. IV verapamil is contraindicated in patients with poor left ventricular function or heart failure, and it should not be administered after pretreatment with oral, or especially IV, beta-blockers. It should not be used for atrial fibrillation associated with preexcitation syndrome because it may result in acceleration of conduction over an antegradely conducting accessory pathway (especially with a short effective refractory period), resulting in a rapid ventricular response and ventricular fibrillation. Diltiazem is an alternative to verapamil, but diltiazem has been associated with lower effective rates.⁷ Diltiazem has the same contraindications as verapamil.

DC cardioversion or pharmacologic conversion with IV ibutilide, propafenone, or flecainide is appropriate for termination of atrial fibrillation with preexcitation.

Beta-Blockers

Among beta-blockers, esmolol, administered as an IV infusion at a rate of 50 to 200 $\mu\text{g/kg/min}$, is the agent of choice because of its rapid onset. More readily available IV metoprolol, atenolol, and propranolol can also be considered (see Table 79-1). Excessive bradycardia caused by AV node blocking agents can be countered with IV injection of atropine, 0.6 to 2.4 mg in divided doses of 0.6 mg.

Other Antiarrhythmic Agents

Because adenosine, verapamil, diltiazem, and beta-blockers are so highly effective in terminating AV nodal reentry tachycardia and AV reentry tachycardia, specific antiarrhythmic drugs such as propafenone, flecainide, sotalol, ibutilide, and amiodarone are seldom needed in the acute setting. Digoxin is not useful because it is often ineffective

FIGURE 79-6 ■ Accelerated junctional rhythm with independent sinus node activity.

and may facilitate conduction over the accessory pathway, shorten the atrial effective refractory period, and promote atrial fibrillation.

Atrial Pacing

In patients with implantable devices, antitachycardia pacing functions can be used to terminate the arrhythmia. However, there is also a risk of inducing atrial fibrillation with a rapid ventricular response in a patient with an antegradely conducting accessory pathway.

Long-Term Management

Patients with AV nodal reentry tachycardia and AV reentry tachycardia should be referred to a cardiologist for electrophysiologic evaluation and long-term management. Both pharmacologic and nonpharmacologic alternatives, including ablation of an accessory pathway, are widely available.

ACCELERATED ATRIOVENTRICULAR RHYTHM

Accelerated AV rhythm is produced by abnormal automaticity in the AV node. It is a narrow QRS complex tachycardia (unless bundle branch block is present), with a ventricular rate ranging from 70 to 250 beats per minute. AV dissociation is also present because the atria are activated normally by the sinus node impulse, while the ventricles are depolarized from an accelerated junctional site (Fig. 79-6). This arrhythmia is commonly due to digitalis toxicity, and drug withdrawal is the usual therapy. If the rate of the AV node pacemaker is not fast, atropine can be given to increase the sinus node discharge rate until the sinus node resumes its dominance.

ATRIAL FIBRILLATION AND ATRIAL FLUTTER

Atrial fibrillation with a fast ventricular response is the most common supraventricular arrhythmia encountered in the emergency department in both younger adults with first-onset arrhythmia and older patients presenting with decompensation. Atrial flutter shares these clinical presentations and requires similar initial therapy. The acute management of both arrhythmias is, therefore, considered together.

Atrial Flutter

Mechanism

Classification of atrial flutter is based on the ECG presentation and electrophysiologic mechanisms. The most common type is typical isthmus-dependent atrial flutter. Incisional reentry atrial flutter occurs after surgical correction for congenital heart disease. There are also various forms of atypical flutters, such as atypical right atrial isthmus-dependent flutter (double-wave and lower loop reentry) and left atrial flutter, in which the circuit contains the pulmonary vein or mitral valve annulus.⁸

Typical, or isthmus-dependent, atrial flutter involves a macroreentrant right atrial circuit around the tricuspid annulus. The wavefront circulates down the lateral wall of the right atrium, through the eustachian ridge between the tricuspid annulus and the inferior vena cava,

FIGURE 79-7 ■ **A**, Typical counterclockwise atrial flutter. F waves are negative in leads II, III, aVF, and V_{5-6} and positive in leads V_{1-2} . **B**, Atrial flutter with 1:1 atrioventricular conduction and a ventricular rate of 270 beats per minute in a patient treated with flecainide. **C**, Atrial fibrillation with fast, uncontrolled ventricular rate.

and up the interatrial septum, giving rise to the most frequent pattern, referred to as *counterclockwise flutter*. Reentry can also occur in the opposite direction (clockwise or reverse flutter).

Electrocardiographic Presentation

Atrial flutter is usually an organized atrial rhythm with an atrial rate typically between 250 and 350 beats per minute. In the more common counterclockwise flutter, F waves are negative in leads II, III, aVF, and V_{5-6} and positive in leads V_{1-2} (Fig. 79-7, A). Clockwise atrial flutter is typically characterized by positive F waves in leads II, III, and aVF and negative waves in leads V_{1-2} .

Treatment with propafenone, flecainide, and amiodarone to prevent recurrent atrial fibrillation without adding an AV blocking agent (beta-blocker or nondihydropyridine calcium antagonist) can organize the arrhythmia into typical atrial flutter with AV conduction of 1:1 or 2:1, producing a ventricular rate response of 150 beats per minute or higher (see Fig. 79-7, B). The probability of 1:1 conduction is increased in the presence of an accessory pathway with a short effective refractory period.

Long-Term Management

The precise mechanism of atrial flutter is important for long-term management (e.g., catheter ablation) but has little influence on the initial approach. Patients with all types of atrial flutter should be referred for electrophysiologic evaluation with a view to ablation. Atrial fibrillation may develop even after successful ablation, and the patient should be followed up carefully.

Atrial Fibrillation

Electrocardiographic Presentation

Atrial fibrillation is defined as rapid oscillations or fibrillatory f waves that vary in size, shape, and timing (see Fig. 79-7, C). The ventricular response rate is variable and depends on the rate and regularity of atrial activity, the refractory properties of the AV node itself, and the balance

between sympathetic and parasympathetic tone. RR intervals are irregular unless the patient has complete AV block or a paced rhythm.

Classification

The clinical classification of atrial fibrillation includes first detected, paroxysmal (up to 7 days), persistent (more than 7 days), long-standing persistent (>1 year), and permanent (accepted) forms of the arrhythmia. Classification is essential for deciding between rhythm restoration and rate control. First-onset atrial fibrillation, if the duration of the episode is less than 48 hours, is a clear indication to restore sinus rhythm by either electrical or pharmacologic means. Because atrial fibrillation may be asymptomatic, the “first detected episode” should not be regarded as necessarily the true onset of the arrhythmia, in which case formal anticoagulation (see later discussion) and rate control may be preferred. Persistent or permanent atrial fibrillation should be treated initially by rate control and anticoagulation when appropriate.

Long-Term Management

Recognition of the pulmonary veins as the source of atrial premature beats or rapid atrial tachycardia that triggers atrial fibrillation or drives the atria prompted the development of ablation techniques that may “cure” the arrhythmia. In symptomatic permanent or persistent atrial fibrillation, AV node ablation and permanent pacing are effective in rate and symptom control. Any patient with first-onset or recurrent atrial fibrillation should be referred to a cardiologist for long-term management.

Acute Management

Acute therapy for atrial flutter and atrial fibrillation depends on the clinical presentation. Emergency electrical cardioversion is indicated for patients with hemodynamic collapse and progressively deteriorating left ventricular systolic function.

Direct-Current Cardioversion

Atrial flutter can be converted with DC shock energy as low as 25 to 50 J, but because a 100-J shock is virtually always successful, it should be considered as the initial shock strength. In recent-onset atrial fibrillation, sinus rhythm can be restored by a shock of 100 J, but it is generally recommended that cardioversion be started with an initial shock energy level of 200 J or greater. In patients with an arrhythmia of unknown duration, heavier individuals, and those with chronic obstructive lung disease and pulmonary emphysema, an initial setting of 300 to 360 J is appropriate. Success may occur on the third or subsequent attempt at an intensity that initially proved ineffective.

Rate Control

Rate control is pertinent to all atrial tachyarrhythmias, particularly if restoration of sinus rhythm is deferred. IV verapamil, diltiazem, and beta-blockers can rapidly control the ventricular response rate in atrial fibrillation² (see Table 79-1), but their efficacy may be less in atrial flutter. The decrease in the ventricular rate (approximately 20%-30%), time to maximal effect (20-30 minutes), conversion rate (12%-25%), and adverse reactions (usually hypotension and bradycardia, although left ventricular dysfunction and high-degree heart block may also occur) are reportedly similar with both classes of drugs. Beta-blockers are preferable if thyrotoxicosis is suspected as a cause of the arrhythmia.

IV digoxin is no longer the treatment of choice when rapid rate control is essential because of the delayed onset of its therapeutic effect (>60 minutes). However, because of its positive inotropic action, digoxin may be safer to use in patients with poor ventricular function and moderately fast ventricular rates. Digoxin may convert flutter to fibrillation, in which rate control is easier to accomplish.

There is evidence that IV amiodarone may be effective in rate control when other AV node blocking agents have no effect on the ventricular response or are contraindicated.

TABLE 79-2 Antiarrhythmic Drugs for Pharmacologic Conversion of Atrial Tachyarrhythmias

| DRUG | ROUTE OF ADMINISTRATION | DOSE | POTENTIAL ADVERSE EFFECTS |
|--------------|---------------------------------------|--|--|
| Flecainide | Oral or intravenous | Loading oral dose 200-300 mg or slow injection 1.5-2 mg/kg over 10-20 min; if no response, infusion 1.5 mg/kg for 1 h, then 0.1-0.25 mg/kg over 24 h | Rapidly conducted atrial flutter, possible deterioration of ventricular function in the presence of organic heart disease, monomorphic ventricular tachycardia |
| Propafenone | Oral or intravenous | Loading oral dose 450-600 mg or 1.5-2 mg/kg over 10-20 min, followed by infusion 5-10 mg/kg if needed | |
| Ibutilide | Intravenous | 1 mg over 10 min; if no response, additional 1 mg | QT prolongation, torsades de pointes, hypotension |
| Amiodarone | Intravenous (preferably central line) | 5-7 mg/kg over 30-60 min, followed by infusion 20 mg/kg for 24 h (total 1200-1800 mg) | Hypotension, bradycardia, QT prolongation, torsades de pointes (?), gastrointestinal upset, constipation, phlebitis |
| Procainamide | Intravenous | 1000 mg over 30 min, followed by 2 mg/min infusion | QRS widening, torsades de pointes, rapid atrial flutter |
| Vernakalant | Intravenous | 3 mg/kg over 10 min; after 15-min break, 2 mg/kg unless arrhythmia terminated | Hypotension, postfibrillation bradycardia |

Pharmacologic Cardioversion

If the arrhythmia is hemodynamically stable and of recent onset, pharmacologic cardioversion can be effective.

Flecainide and Propafenone. Pharmacologic cardioversion of atrial fibrillation can be accomplished with the IC class of antiarrhythmic drugs—flecainide or propafenone—administered orally as a single dose of 300 or 600 mg, respectively (Table 79-2).² Placebo-controlled randomized studies show an efficacy rate of 60% to 80% between the third and eighth hour after drug ingestion.^{9,10} Both oral and IV routes of administration are equally effective, although with IV injection, restoration of sinus rhythm can be achieved more quickly.

Flecainide is given as a slow IV injection of 2 mg/kg over 10 to 30 minutes, up to the maximum dose of 150 mg. Propafenone is administered as a slow IV injection of 1.5 to 3 mg/kg, up to 300 to 600 mg. Because these drugs can significantly slow the atrial rate (from 300-350 beats/min to 200 beats/min), which may result in 1:1 AV conduction, beta-blockers or calcium antagonists with negative dromotropic effects on AV node conduction (verapamil, diltiazem) should be used concomitantly. Other cardiovascular effects include reversible QRS widening and (rarely) left ventricular decompensation. Because of their negative inotropic effects, flecainide and propafenone are contraindicated in patients with severe structural heart disease and a poor ejection fraction.

Class IC drugs are usually ineffective for the conversion of atrial flutter because they slow conduction within the reentrant circuit and prolong the flutter cycle length but rarely interrupt the circuit. These drugs pose the risk of increased (e.g., 2:1 or 1:1) AV conduction. Reported efficacy rates are as low as 13% to 40% with IV flecainide and propafenone.

Ibutilide. The class III agent, ibutilide, is administered intravenously as a 10-minute injection of 1 to 2 mg and is particularly effective in terminating atrial flutter, with a success rate of about 60%. Its administration may be associated with excessive QT interval prolongation, however, because of rapid delayed rectifier potassium current (I_{Kr}) blockade, which may increase the risk of torsades de pointes.^{11,12} It is less effective in atrial fibrillation. Higher doses of ibutilide administered as two successive infusions of 1 mg are usually required to terminate fibrillation. The advantage of ibutilide is that it may be effective in the conversion of arrhythmias of up to 30 days' duration, but the success rate drops significantly to 20% to 30%. The safety of ibutilide in patients with poor left ventricular function is unknown.

Amiodarone. Amiodarone administered intravenously at a dose of 5 mg/kg for 1 hour, followed by an infusion of 20 mg/kg over 24 hours, is effective in converting both atrial fibrillation and flutter, but

the effect is significantly delayed.^{13,14} However, because of its ability to control the ventricular rate, low likelihood of torsades de pointes, and absence of a negative inotropic effect, amiodarone can be used safely in patients with significant structural heart disease and those who are critically ill.

Procainamide and Sotalol. Procainamide administered as a slow IV injection of 1000 mg over 20 to 30 minutes, followed if necessary by an infusion of 2 mg/min over 1 hour, converts atrial flutter or fibrillation of less than 48 hours' duration, but its efficacy is limited in longer lasting arrhythmias.¹⁵ It is less effective than propafenone, flecainide, and ibutilide.

Sotalol is not indicated for the pharmacologic cardioversion of atrial flutter or fibrillation because its efficacy does not exceed 11% to 13%; however, it may satisfactorily control the ventricular rate.

Vernakalant. This drug is given by a short IV infusion (3 mg/kg over 10 minutes). If after a 15-minute waiting period the arrhythmia persists, a second infusion of 2 mg/kg may be given over 10 minutes. In recent-onset (<72 hours) atrial fibrillation, about 50% of cases will terminate on average 12 minutes from the start of the first infusion. Vernakalant may be given to patients with underlying structural heart disease but not to patients with grades II/IV congestive heart failure. Proarrhythmia effects are uncommon, but hypotension and posttermination bradycardia may occur.¹⁶

The choice of an antiarrhythmic agent for cardioversion is illustrated in Figure 79-8.

Atrial Pacing

Burst overdrive atrial pacing can terminate atrial flutter in about 80% of cases and is feasible after cardiac surgery, when patients frequently have epicardial atrial pacing wires, or in patients with implantable dual-chamber pacemakers and defibrillators. High-frequency (50 Hz or 3000 beats/min) atrial pacing is available in some of the latest models for the termination of early-onset atrial fibrillation, but its efficacy has not yet been established. Atrial burst overdrive pacing may induce sustained atrial fibrillation, although short periods of fibrillation often precede conversion to sinus rhythm.

Anticoagulation

Anticoagulation is imperative if the arrhythmia persists for more than 24 to 48 hours or if its duration is unknown. Atrial flutter and atrial fibrillation pose similar risks of thromboembolism, and the same criteria for anticoagulation should be applied in patients with either arrhythmia. In hemodynamically stable arrhythmias of more than 48 hours' or of unknown duration, rate control and 3 weeks' anticoagulation with warfarin (international normalized ratio 2.0 to 3.0) should

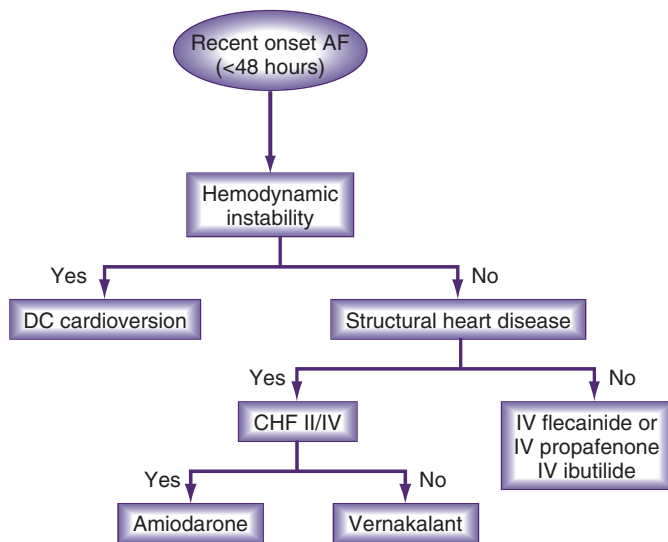

FIGURE 79-8 ■ Choice of antiarrhythmic for pharmacologic cardioversion of atrial fibrillation.

be considered before any intervention (electrical or pharmacologic cardioversion, catheter ablation).¹⁷

Transesophageal Echocardiography–Guided Cardioversion

If, for any reason, deferral of cardioversion is not indicated, the transesophageal echocardiography–guided approach, with short-term anticoagulation using low-molecular-weight heparin, is a safe and effective alternative.¹⁸ It may be clinically beneficial in patients with recent-onset arrhythmias or in individuals at high risk of bleeding complications during prolonged anticoagulation therapy.¹⁹ Compared with unfractionated heparin, low-molecular-weight heparin therapy does not involve prolonged IV administration or laboratory monitoring and, therefore, has the potential to greatly simplify cardioversion-related anticoagulation therapy in low-risk individuals. Postcardioversion anticoagulation should be considered if atrial fibrillation has been present for 48 hours or more, or if thromboembolic risk factors are present.^{17,20}

■ ATRIAL TACHYCARDIA

Mechanism

The mechanism of atrial tachycardia is attributed to enhanced automaticity, triggered activity, or intraatrial reentry. Macroreentrant atrial tachycardia often occurs after surgery for congenital heart disease. Focal atrial tachycardia typically originates along the crista terminalis in the right atrium, in the pulmonary veins entering the left atrium, or around one of the atrial appendages.

Electrocardiographic Presentation

The heart rate varies from 120 to 250 beats per minute, P waves precede the QRS complexes, and PP intervals are regular (see Fig. 79-5, B). The PR interval is linked to the rate of the tachycardia and is longer than in sinus rhythm at the same rate. P-wave morphology is usually different from that observed during sinus rhythm and depends on the site of origin. Left atrial tachycardia presents with negative P waves in leads I, aVL, V₅, and V₆. Automatic atrial tachycardia may present as an incessant variety, leading to tachycardia-induced cardiomyopathy.

FIGURE 79-9 ■ Atrial tachycardia with varying atrioventricular block due to digitalis toxicity.

Atrial Tachycardia with Atrioventricular Block

Tachycardia with AV block occurs commonly in patients with organic heart disease, and in 50% to 75% of cases, it is due to digitalis toxicity (Fig. 79-9). Digoxin-specific antibody fragments are available for the reversal of life-threatening overdose.

Multifocal Atrial Tachycardia

This tachycardia presents as rapid, irregular atrial activity with discrete P waves of varying morphology and is considered a transitional rhythm between atrial tachycardia and fibrillation. However, it may occur in patients with chronic severe pulmonary disease as a result of theophylline or beta-agonist overdose. Elimination of the causative factor may reduce the need for antiarrhythmic therapy. IV verapamil can accomplish rate control.

Acute Management

DC cardioversion converts atrial tachycardia based on the reentry mechanism or triggered activity, but it may not terminate automatic tachycardia. Similarly, atrial overdrive pacing may slow the tachycardia rate but seldom suppresses the automatic focus.

It is generally accepted that beta-blockers and calcium antagonists, particularly verapamil, can either terminate the tachycardia or produce rate control. Adenosine can terminate atrial tachycardia, but the most common response to adenosine is to create AV block and, thereby, reveal the unaffected tachycardia (see Fig. 79-5, B and C).

Flecainide, propafenone, sotalol, and amiodarone are effective in converting atrial tachycardia. If the arrhythmia occurs as a result of digitalis intoxication, therapy includes the cessation of digoxin and IV administration of potassium.

Long-Term Management

Patients with atrial tachycardia should be referred to a cardiologist because the arrhythmogenic focus can be found and ablated in up to 86% of cases.

■ INAPPROPRIATE SINUS TACHYCARDIA

Inappropriate sinus tachycardia is a persistent increase in resting heart rate unrelated or out of proportion to the level of physical or emotional stress. It is found predominantly in women and is not uncommon in health professionals. Sinus tachycardia due to intrinsic sinus node abnormalities such as enhanced automaticity or abnormal autonomic regulation of the heart, with excess sympathetic and reduced parasympathetic input, is not unusual. The main therapy is beta-blockers, although ivabradine, a drug that blocks the main current responsible for diastolic depolarization in the sinus node, is being increasingly used in Europe.²¹ In general, sinus tachycardia is a secondary phenomenon, and the underlying cause should be actively investigated. Depending on the clinical setting, acute causes include fever, hypotension, infection, anemia, thyrotoxicosis, hypovolemia, acute heart failure, acute pulmonary embolism, and shock. Sinus tachycardia may be associated with the abuse of drugs such as amphetamines.

KEY POINTS

1. Supraventricular tachycardia (SVT) is characterized by narrow QRS complexes, but differentiating SVT from ventricular tachycardia may be necessary when bundle branch block, rate-dependent aberrancy, and antidromic atrioventricular (AV) reentry tachycardia are present.
2. If the diagnosis of SVT cannot be proved, the arrhythmia should be treated as ventricular tachycardia.
3. Immediate direct-current (DC) cardioversion is the treatment for any hemodynamically unstable tachycardia.
4. In hemodynamically stable paroxysmal junctional tachycardias (AV nodal reentry tachycardia and AV reentry tachycardia), vagotonic maneuvers should be tried first because they may terminate tachycardia in about 50% of patients without the need to resort to pharmacologic therapy.
5. Intravenous (IV) adenosine, verapamil, and esmolol are first-line drug therapies for paroxysmal junctional tachycardias, but adenosine and verapamil should not be used for wide complex tachycardias and atrial fibrillation with preexcitation.
6. DC cardioversion or pharmacologic conversion with IV ibutilide or flecainide is appropriate for the termination of atrial fibrillation associated with preexcitation syndrome.
7. IV verapamil, diltiazem, esmolol, metoprolol, and propranolol can rapidly accomplish rate control in atrial fibrillation but may be less effective in atrial flutter.
8. Beta-blockers are preferable in atrial fibrillation associated with thyrotoxicosis.
9. Pharmacologic cardioversion of atrial fibrillation in the absence of severe underlying heart disease can be attained using oral or IV flecainide or propafenone, vernakalant, and IV ibutilide, but the last is more effective in atrial flutter.
10. Propafenone, flecainide, and vernakalant may result in atrial flutter with slow atrial rates and 2:1 or 1:1 AV conduction; verapamil, diltiazem, or beta-blockers should be available to treat this complication. Ibutilide can significantly prolong the QT interval and cause polymorphic ventricular tachycardia that, if sustained, may require DC cardioversion.
11. IV amiodarone should be considered as first-line drug therapy in patients with severely impaired left ventricular function.
12. Accelerated AV rhythm and atrial tachycardia with AV block commonly occur as a result of digitalis toxicity; digitalis withdrawal is the usual therapy.
13. Anticoagulation is indicated if atrial fibrillation or flutter persists for more than 48 hours or if the duration is unknown; anticoagulation and rate control should be the initial therapy in these patients.
14. An alternative approach is transesophageal echocardiography, to exclude the presence of atrial thrombi or dense spontaneous echocontrast, and short-term anticoagulation with low-molecular-weight heparin, followed by DC or pharmacologic cardioversion.
15. Patients with paroxysmal junctional tachycardias, atrial tachycardia, atrial flutter, and first-onset or recurrent atrial fibrillation should be referred to a cardiac electrophysiologist/cardiologist for assessment and long-term management planning; effective nonpharmacologic therapies are available for these arrhythmias.

ANNOTATED REFERENCES

Albers GW, Dalen JE, Laupacis A, et al. Antithrombotic therapy in atrial fibrillation. *Chest* 2001;119:194S–206S.

This paper focuses on the prevention of stroke in nonrheumatic atrial fibrillation and flutter and provides expert recommendations regarding risk stratification, anticoagulation strategies, cardioversion (including transesophageal echocardiography-guided cardioversion), and long-term management of patients at risk of thromboembolism. It contains a complete review of the evidence base for anticoagulation in atrial fibrillation.

Blomström-Lundqvist C, Scheiman MM, Aliot EM, et al. ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines (Writing Committee to develop guidelines for the management of patients with supraventricular arrhythmias). *J Am Coll Cardiol* 2003;42:1493–1531.

These practice guidelines describe a range of generally accepted approaches to the diagnosis and management of supraventricular tachyarrhythmias (excluding atrial fibrillation) and provide insight into the multiple mechanisms defined by electrophysiologic studies, with a focus on both acute and long-term therapies.

Camm AJ. Atrial fibrillation: is there a role for low-molecular-weight heparin? *Clin Cardiol* 2001;24:115–119.

This review paper summarizes evidence emerging from clinical studies that clearly supports both the use of transesophageal echocardiography-based cardioversion protocols and the introduction of low-molecular-weight heparin for anticoagulation in atrial fibrillation. Clinical settings in which low-molecular-weight heparin may offer advantages over unfractionated heparin and warfarin are discussed.

Fuster V, Rydén LE, Asinger RV, et al. Task force report: ACC/AHA/ESC guidelines for the management of patients with atrial fibrillation. *Eur Heart J* 2001;22:1852–1923.

These guidelines incorporate a comprehensive review of the latest information about the classification, epidemiology, mechanisms, and clinical presentations of atrial fibrillation. Practical approaches to acute and long-term management of this arrhythmia are discussed at length. An extensive list of references covers various aspects of atrial fibrillation.

Mehta D, Wafa S, Ward DE, Camm AJ. Relative efficacy of various physical manoeuvres in the termination of junctional tachycardia. *Lancet* 1988;1:1181–1185.

This paper compares the ability of four vagotonic physical maneuvers to terminate paroxysmal supraventricular tachycardias that involve the AV node as part of their reentrant circuits. It shows that these tachycardias can be terminated without resorting to pharmacologic therapy in more than half of patients. The paper provides a detailed methodologic description and explains the physiologic effects of vagotonic maneuvers.

Cardiac arrhythmias are common in critically ill patients and a frequent reason for hospital admission to areas with capability for continuous electrocardiographic monitoring and personnel trained in their recognition and management (e.g., ICUs and telemetry units).

Arrhythmias are supraventricular if they originate above the atrioventricular (AV) node in atrial tissue or pulmonary veins. They may compromise stroke volume and create hemodynamic instability by excessive heart rate and/or reduced ventricular filling after losing the atrial contribution to preload. However, in the absence of accessory conduction pathways bypassing the AV node (e.g., Wolf-Parkinson-White syndrome), supraventricular arrhythmias are rarely life threatening and may be managed without immediate urgency by pharmacologic or electrical means. In contrast, arrhythmias that originate in ventricular structures, such as ventricular tachycardia (VT) and ventricular fibrillation (VF), may be life threatening and require immediate treatment.

NORMAL ELECTROPHYSIOLOGY

Anatomic Synopsis

The electrical impulse originates in the sinoatrial (SA) node, located high on the right atrium near its junction with the superior vena cava (Fig. 80-1). The impulse propagates through muscle fibers and specialized internodal pathways (composed of Purkinje-type fibers) to converge on the AV node, located in the interatrial septum near the tricuspid valve. The impulse then travels through the bundle of His, its left and right branches, and the Purkinje system to activate simultaneously both ventricles. A ring of fibrous tissue interposed between the atria and the ventricles prevents spread of the impulse through muscle fibers, enabling the AV node to function as relay and filter, preventing 1:1 conduction under conditions of very rapid atrial activation, such as atrial flutter (rate ~300/s) or atrial fibrillation (rate ~600/s).

Action Potential and Pacemaker Activity

Action Potential

Action potentials initiate and propagate the electrical impulse, ultimately reaching cardiomyocytes signaling Ca^{2+} -induced Ca^{2+} release from the sarcoplasmic reticulum to activate contractile proteins. Action potentials result from a coordinated sequence of depolarization and repolarization of polarized cells following opening and closing of ion channels, carrying electrical currents through the plasma membrane. The main currents result from influx of Na^+ and Ca^{2+} (inward currents) and efflux of K^+ (outward currents).¹⁻³

Cells from the Purkinje system and muscle tissue have stable resting potential of approximately -90 mV (negative inside), largely the result of a K^+ current known as *inward rectifier* (I_{K1}). I_{K1} “anchors” the membrane potential to a voltage close to the equilibrium potential of potassium and is turned off during depolarization. Triggering an action potential requires depolarization between -70 and -80 mV—that is, the activation threshold for fast voltage-gated Na^+ channels driving a Na^+ current (I_{Na})³—and typically occurs upon arrival of another action potential. The I_{Na} drives the membrane potential toward the Na^+ equilibrium potential, reversing the membrane potential to approximately

$+20$ mV (overshoot). This sequence is *phase 0* of the action potential, which is followed by repolarization in four phases (Fig. 80-2).

Phase 1 is early repolarization after rapid inactivation of I_{Na} and rapid activation and inactivation of a “transient” K^+ current (I_{To}) carried by two subpopulations of K^+ channels driving a “fast” recovering (I_{Tof}) and a slowly recovering (I_{Tos}) current. I_{Tof} appears to be the predominant contributor to I_{To} in ventricular myocardium.⁴ Because K^+ channels carrying I_{To} are expressed in the subepicardium and mid-myocardium but not in the subendocardium, I_{To} contributes to repolarization inhomogeneity.⁵

Phase 2 is mid-repolarization (plateau phase), which results predominantly from a Ca^{2+} current carried by the slow and prolonged opening of L-type voltage-gated Ca^{2+} channels ($\text{I}_{\text{Ca-L}}$).^{6,7} These channels open during *phase 0* at a membrane potential of -30 to -40 mV; they are inactivated by increased cytosolic Ca^{2+} and are strongly regulated by neurotransmitters.

Phase 3 is late repolarization, which follows closing of Ca^{2+} channels and opening of K^+ channels with slow activation kinetics that carry currents known as *delayed rectifiers* (I_{K}), which have a rapid (I_{Kr}) and a slow (I_{Ks}) component.^{8,9} Both are implicated in heritable forms of the long QT syndrome.¹⁰ Opening of I_{K1} —the main contributor to the resting potential—also contributes to repolarization.

Phase 4 is the return to resting membrane potential, the interval during which ionic balance is restituted, largely through the Na^+/K^+ pump.

Pacemaker Activity

Cells of the SA and AV nodes lack voltage-gated Na^+ channels; therefore, phase 0 is carried by $\text{I}_{\text{Ca-L}}$.¹¹ Because of their slower opening kinetics, phase 0 is slanted and in part responsible for the slower SA and AV nodes’ conduction velocity (~ 50 cm/s) relative to the His-Purkinje system (~ 400 cm/s) and muscle cells (~ 100 cm/s). Pacemaker activity of SA and AV node cells results from slow phase 4 depolarization (known as *prepotential* or *pacemaker potential*) to about -40 mV. Slow depolarization involves a background Na^+ current ($\text{I}_{\text{Na-B}}$), a decay of K^+ currents, and the opening of T-type voltage-gated Ca^{2+} channels ($\text{I}_{\text{Ca-T}}$). Cells of the His-Purkinje system have latent pre-potential activity and can become active when SA or AV node activity is depressed or their impulses are blocked (i.e., “escape rhythm”). Muscle cells exhibit pre-potential activity only under abnormal circumstances.

The preceding description is brief and oversimplified. Various other ion channels, antiporters, pumps, and receptors modulate the action potential. An example is the nonselective cationic channel gated at resting potential by intracellular Ca^{2+} . This channel produces an inward Na^+ current (I_{NS})¹² that may contribute to delayed afterdepolarizations after Ca^{2+} release from the sarcoplasmic reticulum. $\text{I}_{\text{k(atp)}}$ is a K^+ current carried through channels inhibited by adenosine triphosphate (ATP) and opened under conditions of ischemia and hypoxia. $\text{I}_{\text{k(atp)}}$ is the main contributor to action potential shortening and the characteristic ST-segment elevation observed during myocardial ischemia.^{13,14}

The sarcolemmal $\text{Na}^+/\text{Ca}^{2+}$ exchanger is another important modulator of the action potential. Because it exchanges one Ca^{2+} for three Na^+ , it generates a current ($\text{I}_{\text{Na/Ca}}$) whose direction depends on Na^+ and Ca^{2+} gradients and the membrane potential.^{14,15}

Adrenergic receptor stimulation may also modulate the action potential by modifying channel activity.¹⁶⁻¹⁸ For example, β -adrenoceptor

FIGURE 80-1 ■ Conduction system of the heart. AV, atrioventricular; SA, sinoatrial.

FIGURE 80-2 ■ Action potential of a cardiac muscle cell, depicting the main underlying inward and outward currents and respective gene products. Distinctive phases of the action potential are numbered. Voltage (mV) refers to the potential on the intracellular side of the plasma membrane relative to an outside reference. Notice that the resting potential is negative inside at approximately -90 mV, indicating the cell at rest is polarized (phase 4). The beginning of the action potential is signaled by rapid reduction in such potential, with the inside voltage reaching 0 mV (depolarization) and then becoming transiently positive (overshoot) during phase 0, to be followed by phase 1, 2, and 3 as voltage returns to resting potential on phase 4.

stimulation increases I_{Ca-L} activity and Ca^{2+} influx, enhancing inotropic action. β -Adrenoceptor stimulation also activates K^+ channels, shortening the action potential duration.¹⁹ α_1 -Adrenoceptor stimulation acting via G-protein on the Na^+/K^+ pump, K^+ channels, and phospholipase C and can alter impulse initiation and repolarization—an effect linked to triggered arrhythmias via early and delayed afterdepolarizations and abnormal automaticity during ischemia and reperfusion.^{20,21}

Cardiomyocytes can also react to mechanical forces through stretch-activated ion channels and other mechanisms, including mechanical modulation of Ca^{2+} handling and interaction with other mechanosensitive cells.^{22,23} These mechanisms are in part involved in commotio cordis,²⁴ precordial thump,²⁵ and fist pacing.²⁶

MECHANISMS OF VENTRICULAR TACHYARRHYTHMIAS

Abnormalities in impulse generation and conduction are responsible for the genesis and maintenance of ventricular tachyarrhythmias.

Abnormalities in Impulse Generation

Abnormalities in impulse generation are generally the result of automaticity or triggered activity.

Automaticity

Automaticity is the emergence of ectopic pacemaker activity resulting from enhanced normal automaticity or development of abnormal automaticity.

Enhanced normal automaticity occurs when cells whose pacemaker potentials are normally suppressed by the SA node (e.g., AV node or His-Purkinje system) fire at rates that escape such suppression. This phenomenon may result from effects on phase 4 prepotentials yielding earlier development of action potentials (i.e., less maximal polarization, faster depolarization, or lower threshold potential) or from shortening of the action potential duration with earlier return to phase 4. Enhanced normal automaticity is usually the result of adrenergic stimulation.

Abnormal automaticity refers to impulses originating in cells without intrinsic pacemaker potential and typically occurs by generation of depolarizing currents during phase 4 (e.g., ischemia).²⁷ Abnormal automaticity can develop in atrial and ventricular muscle cells and in specialized tissues other than the SA and AV node. Examples include accelerated idioventricular rhythms and some VTs developing 24 to 72 hours after acute myocardial infarction.²⁸

Triggered Activity

Triggered activity refers to arrhythmias that arise from afterdepolarizations, defined as alterations in membrane potential that occur during repolarization without an external trigger.²⁹ Afterdepolarizations are considered early if they develop during phase 2, phase 3, or early phase 4 of the action potential and are characterized by transient retardations in repolarization (Fig. 80-3). Early afterdepolarizations of sufficient magnitude can trigger an “extra” action potential and are typically associated with conditions that prolong the action potential (e.g., increased sympathetic tone, exogenous catecholamines, hypoxia, acidosis, bradycardia, etc.), enabling increased Ca^{2+} entry through I_{Ca-L} ³⁰ and potentially triggering torsades de pointes.

Afterdepolarizations are considered delayed if they develop in late phase 4 and can also reach the threshold for triggering an action potential (see Fig. 80-3). The main underlying abnormality is intracellular Ca^{2+} overload that triggers Ca^{2+} release from the sarcoplasmic reticulum³⁰ and depolarizing currents (i.e., inward $I_{Na/Ca}$ currents). Delayed afterdepolarizations are classically associated with digitalis toxicity; however, they can also occur with myocardial stretch, hypertrophy, catecholamines, ischemia, and reperfusion. In heart failure, increased expression of the Na^+-Ca^{2+} exchanger along with abnormalities in the ryanodine receptor predispose to delayed afterdepolarizations.

Abnormalities in Impulse Conduction (Reentry)

Abnormalities in impulse conduction leading to reentry account for the vast majority of sustained ventricular tachyarrhythmias. Reentry occurs when a propagating impulse reenters and reexcites a region of previously excited tissue after its refractory period is over. Several

FIGURE 80-3 ■ Afterdepolarizations (dotted lines). Early afterdepolarizations are retardations in repolarization with prolongation in action potential duration (upper figure). Delayed afterdepolarizations represent spontaneous depolarizations that occur after repolarization is over (lower figure). Afterdepolarizations that reach threshold trigger an action potential.

FIGURE 80-4 ■ Ring model of reentry.

forms of reentry have been described, including circus movement, phase 2, and reflection.³¹

Circus Movement

Circus movement is the most widely studied reentry model and encompasses four distinct models: ring, leading circle, figure of eight, and spiral wave.

The *ring model* is the simplest³² and is useful for illustrating the basic mechanism of reentry (Fig. 80-4). The ring model requires two contiguous paths separated by unexcitable tissue. One path (*b* in Fig. 80-4) has a zone of unidirectional block whereas the other path (*a* in Fig. 80-4) allows slow but bidirectional conduction. Once the impulse that is traveling path *a* reaches path *b*, it propagates retrogradely to subsequently reenter path *a*. To establish reentry, the circling impulse wavelength must be shorter than the reentry circuit path length, allowing its leading edge to find tissue in an excitable state. The circling impulse wavelength is the product of the conduction velocity and refractory period; conditions that slow conduction or shorten refractoriness favor reentry.

Reentry is usually triggered by the arrival of a premature beat. Unidirectional block may result from increased refractoriness caused by anatomic abnormalities (e.g., fibrosis, accessory pathway, bundle branch block) or functional defects (e.g., ischemia, action of drugs). The ring model commonly involves AV accessory pathways and the AV node.

The leading circle model is similar to the ring model but without requiring anatomic obstacles and can develop in structurally uniform myocardium by a properly timed premature impulse.³³

The figure-of-eight model was first described in experimental myocardial infarction. It encompasses two reentry circuits moving alongside a functional conduction block (ischemia or infarct) in opposite directions, forming a pretzel-like configuration.³⁴

The spiral wave model is a more complex version of the leading circle model. This model involves a core and filaments and can be described as reentry in two dimensions.³⁵ It has been used to explain monomorphic and polymorphic VTs as well as VF. In monomorphic VT, the spiral wave is anchored and unable to drift, whereas in polymorphic VTs such as torsades de pointes, the spiral is thought to drift. In VF, the spiral wave is thought to break up into multiple rotating spiral waves that continuously extinguish and recreate. Yet, some authors have proposed a single rapidly shifting spiral, and others have postulated a stationary rotor whose frequency of excitation is exceedingly high, resulting in multiple areas of intermittent block.³⁶

Phase 2

Phase 2 reentry refers to local reexcitation consequent to repolarization heterogeneity with areas of markedly shortened repolarization—essentially obliterating phase 2 of the action potential—next to areas of normal repolarization. Local reexcitation may precipitate VT during myocardial ischemia.³⁷ Action potentials of normal duration may alternate with ones of shorter duration during myocardial ischemia, yielding beat-to-beat alternans (temporal dispersion) and site-to-site alternans (spatial dispersion) and promote regions with conduction block and regions with injury current, leading to reentry and ventricular tachyarrhythmias. The degree of spatial and temporal dispersion progresses during ischemia, suggesting this mechanism may be an important trigger of VT and VF during acute myocardial ischemia.³⁸ In the surface ECG, dispersion of the action potential duration manifests as T-wave alternans, a predictor of VF.³⁹

Reflection

Reflection refers to a back-and-forth propagation of the impulse over the same functionally unexcitable tissue, with recurrent activation of the proximal region as a result of electrotonic currents.⁴⁰ The area of unexcitable tissue can result from ischemia and lead to extrasystolic activity. Reflection differs from classic reentry in that the impulse travels along the same pathway in both directions.

CONDITIONS PREDISPOSING TO VENTRICULAR ARRHYTHMIAS

Channelopathies

The term *channelopathies* has been coined to identify a group of diseases caused by abnormalities in ion channels.^{41,42} These abnormalities distort the action potential, primarily accentuating the inherent instability of repolarization and increasing the risk of polymorphic VT of the torsades de pointes type. Channelopathies may be hereditary or acquired.

Hereditary Channelopathies

Most hereditary channelopathies originate from mutations in genes encoding for Na⁺, K⁺, and Ca²⁺ channels and are largely represented by the congenital long QT syndrome (LQTS),⁴³⁻⁴⁷ Brugada syndrome,⁴⁸⁻⁵¹ and catecholaminergic polymorphic ventricular tachycardia (CPVT).⁵²⁻⁵⁴ Less common channelopathies include the short QT syndrome (SQTs)⁵⁵ and early repolarization syndrome (ERS).⁵⁶⁻⁵⁸ All contribute with varying penetrance to sudden cardiac arrest in young individuals.^{59,60}

Long QT Syndrome (LQTS). The LQTS was first described in 1957 by Jervell and Lange-Nielsen in patients with long QT intervals, episodes of torsades de pointes, and deafness.⁶¹ The syndrome is transmitted by autosomal recessive inheritance and is known as the *Jervell*

and Lange-Nielsen syndrome. In 1963 and 1964, Romano and colleagues⁶² and Ward⁶³ independently reported patients with an almost identical disorder but without deafness. The syndrome is transmitted by autosomal dominant inheritance and is known as the *Romano-Ward syndrome*. The two syndromes are primarily responsible for LQTS1 and account for nearly 50% of all genotyped families. LQTS2 accounts for nearly 40% and LQTS3 for about 5%. The remaining types are much less frequent⁶⁴ and are listed in Table 80-1.

The common mechanistic thread is a perturbed balance between I_{Na} and I_K during phase 2 of the action potential, yielding prolongation of repolarization, slowed I_{Ca-L} inactivation, late Ca^{2+} influx, and early afterdepolarizations predisposing to torsades de pointes.⁶⁵

LQTS should be suspected in young individuals who present with syncope or episodes of sudden cardiac arrest precipitated by exercise, emotional distress, or conditions that prolong the QT interval. A family history of unexplained syncope or sudden cardiac arrest should raise

suspicion. The diagnosis should be suspected when the corrected QT interval ($QT_c = QT_{(ms)} \cdot \sqrt{R - R_{(s)}}$) exceeds 470 ms in males (normal <422 ms) and 480 ms in females (normal <432 ms). Genetic testing for identifying the various LQTS subtypes is becoming readily available.⁶⁴

In addition to LQTS, recent population studies have shown that even milder prolongation of the QT_c in adults (>450 ms in men and >470 ms in women) increases the risk of sudden cardiac arrest.⁶⁶

Recently, mutations in the calmodulin genes *CALM1* and *CALM2* have been shown to cause an extremely severe form of LQTS, with QT prolongation greater than 600 ms, T-wave alternans, cardiac arrest in infancy, and intermittent 2:1 atrioventricular block.^{67,68}

The management starts with discontinuing all drugs known to prolong the QT interval and correcting electrolyte imbalances and metabolic conditions that could trigger torsades de pointes. Restriction of participation in athletic activities is generally recommended along with use of β -blockers and antiarrhythmic agents (e.g., mexiletine or

TABLE 80-1 Congenital Long QT Syndromes

| TYPE | FREQUENCY (%) | GENE CHROMOSOME | PROTEIN | MECHANISM, MUTATION EFFECT | GENETIC TRANSMISSION | CLINICAL FEATURES | SYNDROME TYPE |
|--------|---------------|---------------------------|---|---|---------------------------------|---|---------------|

flecainide). In selected cases an implantable defibrillator, cardiac sympathetic denervation, or both may be necessary.

Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT). CPVT is a highly malignant arrhythmogenic disorder that may present with sudden cardiac arrest induced by exercise or emotion, typically in children or adolescents without structural heart disease.⁵⁴ CPVT is associated with two main mutations that affect Ca^{2+} handling by the sarcoplasmic reticulum. One involves an autosomal dominant mutation on the ryanodine receptor gene *RyR2* (i.e., CPTV type 1). The mutation reduces the affinity of FKBP12.6 for *RyR2*, lowering the threshold for Ca^{2+} release from the sarcoplasmic reticulum.⁵³ β -Adrenergic stimulation intensifies Ca^{2+} release and in part explains the effects of exercise and emotion.

The second is an autosomal recessive mutation on the calsequestrin 2 gene *CASQ2* (CPVT type 2). Within the sarcoplasmic reticulum, the *CASQ2* protein serves as the major Ca^{2+} reservoir. The mutation causes a negatively charged domain that alters Ca^{2+} binding.⁵²

The electrocardiogram at rest is typically normal, with occasional U waves and bradycardia. β -Blockers are the cornerstone of therapy, with an implantable cardioverter defibrillator (ICD) indicated in high-risk individuals. Flecainide inhibits the *RyR2* receptor and can suppress or terminate the arrhythmias. Familial screening is indicated once the diagnosis is established.

Short QT Syndrome (SQTS). SQTS is a more recently described syndrome⁵⁵ characterized by tall and peaked T waves with QT intervals less than or equal to 300 milliseconds insensitive to changes in heart rate in structurally normal hearts. Individuals are at risk of developing atrial fibrillation and VF. A family history may be present including sudden death at a young age.

The shortened QT interval results from increased outward K^{+} currents during phase 2 and phase 3 of the action potential associated with autosomal dominant mutations in the *KCNH2*, *KCNJ2*, and *KCNQ1* genes.

ICD implantation is a class I recommendation in survivors of cardiac arrest and in patients with spontaneous sustained VT with or without syncope. Among various drugs, quinidine and sotalol could be effective by prolonging the QT interval.⁵⁵

Brugada Syndrome. Another important hereditary channelopathy is the Brugada syndrome described in 1992 by the Brugada brothers,⁴⁸⁻⁵¹ who reported sudden cardiac arrests in individuals with structurally normal hearts but ST-segment elevation in V_1 to V_3 and a QRS resembling right bundle branch block.

Brugada syndrome exhibits predominantly an autosomal dominant pattern of inheritance, with an average worldwide prevalence of 5:10,000.⁶⁹ Mutations have been identified in ten genes.⁷⁰ Loss of function caused by a mutation in the *SCN5A* gene (encoding for the I_{Na} α -subunit) accounts for approximately 20% of cases. The other 80% depend on mutations involving *GPD1-L*, *CACNA1C*, *CACNB2*, *SCN1B*, *KCNE3*, *SCN3B*, *MOG1*, *KCNE5*, and *KCND3*.⁷⁰

The predominant genetic mechanism in the *SCN5A* gene is an accelerated inactivation of I_{Na} leaving I_{To} unopposed, resulting in rapid repolarization with shortened action potential duration. In addition, the predominant epicardial expression of I_{To} allows normally depolarized endocardium to reexcite, prematurely repolarizing the epicardium and generating reentry, which in turn can precipitate polymorphic ventricular tachycardia.

The ST-segment elevation can adopt various shapes related to severity of the $\text{I}_{\text{Na}}/\text{I}_{\text{To}}$ imbalance. With increasing severity, saddleback, coved, and triangular shapes are recognized.⁶⁵ These changes are dynamic and can change in the same affected individual as shown in Figure 80-5.

Brugada syndrome exhibits variable expressivity, reduced penetrance, and “mixed phenotypes” wherein families may include members with Brugada syndrome as well as members with SQTS, LQTS, atrial fibrillation, disease of the conduction system, and even structural heart disease.⁶⁹

Genetic testing can be useful when there is personal and family history along with the characteristic electrocardiographic pattern identified at rest or after drug challenge.

FIGURE 80-5 ■ Representative tracings in a patient with Brugada syndrome, demonstrating dynamic changes in V_1 to V_2 after resuscitation from cardiac arrest. Type 1 refers to the coved-type ST-T configuration, whereas type 2 and type 3 refer to the saddleback ST-T configuration. (From Wilde AA, Antzelevitch C, Borggrefe M, Brugada J, Brugada R, Corrado D, et al. Study Group on the Molecular Basis of Arrhythmias of the European Society of Cardiology. Proposed diagnostic criteria for the Brugada syndrome: consensus report. *Circulation* 2002;106:2514–9.)

Patients with Brugada syndrome may have concealed or intermittent forms, unmasked (or precipitated) by febrile states, vagotonic agents, α -adrenergic agonists, β -adrenergic blockers, tricyclic or tetracyclic antidepressants, a combination of glucose and insulin and hypokalemia, and alcohol and cocaine toxicity.⁷¹ Concealed Brugada syndrome can be unmasked by class IC antiarrhythmic drugs; e.g., ajmaline (1 mg/kg intravenous in 5 minutes), flecainide (2 mg/kg intravenous in 10 minutes), or procainamide (10 mg/kg intravenous in 10 minutes). Such testing carries a 0.5% risk of precipitating VF. Ajmaline is favored because of its shorter half-life.⁷² The test is considered positive if an additional 1-mm ST-segment elevation (0.08 seconds after the J point) occurs in leads V_1 , V_2 , and V_3 . The test has high specificity and high sensitivity (94% and 80%, respectively).⁷³

The preferred management of Brugada syndrome is an ICD.⁵⁰ However, quinidine and hydroquinidine can prevent spontaneous changes in the electrocardiogram (ECG) and reduce the risk of VT and VF, presumably through inhibition of I_{To} .^{74,75} Ablation of the substrate located in the anterior epicardial region of the right ventricular outflow tract recently has been shown to reduce the episodes of VF in patients with ICD.⁷⁶

Early Repolarization and Early Repolarization Syndrome. Early repolarization is generally defined by a J-point elevation on the ECG greater than 0.1 mV in two adjacent leads with a slurred or notched morphology. This common condition affects 1% to 5% of individuals.⁵⁶ Early repolarization was previously thought to be a completely benign finding; however, studies and case reports seem to suggest a higher risk of arrhythmias, mainly idiopathic ventricular fibrillation, in such patients.^{57,58}

Early repolarization is mainly sporadic; however, genetic inheritance is being noted in the literature, and a wide array of both loss and gain of function genetic mutations have been reported.^{74,77} Some studies have stratified the risk of developing arrhythmia based on the patterns of early repolarization on ECG. Type 1 is associated with early

repolarization in the lateral leads. This pattern is thought to be largely benign. Type 2 is associated with early repolarization in the inferior or inferolateral leads and is associated with a moderate level of risk. Type 3 is associated with early repolarization in the inferior, lateral, and right precordial leads and appears to be associated with the highest relative risk.⁷⁸ Type 4, also known as Brugada syndrome, is described in detail earlier in this chapter.

It is important to differentiate between early repolarization in which only the classic ECG findings are found in an asymptomatic individual with early repolarization syndrome (ERS), which includes the classic ECG findings of early repolarization in a survivor of sudden cardiac death with evidence of VF after an extensive workup has ruled out any other cardiac abnormalities.

A class 1 recommendation for patients with asymptomatic early repolarization on the ECG is to observe. In this patient population in the acute setting of VF requiring defibrillation, isoproterenol was shown to be effective in suppressing the episode.⁷⁹ ICD is a class 1 recommendation in patients with ERS who are survivors of SCD.

Acquired Channelopathies

Acquired channelopathies are common with advanced heart failure and are an important factor affecting the expression of ion channels regardless of the primary etiology.⁸⁰ Downregulation of I_{To} and I_{K1} can occur, causing QT prolongation, possibly an adaptive response allowing a longer interval for excitation-contraction. Yet it predisposes to inhomogeneous repolarization, early afterdepolarizations, and triggered arrhythmias. Upregulation of the Na^+/Ca^{2+} exchanger can also occur, a response in part to downregulation of the sarcoplasmic reticulum Ca^{2+} -ATPase (SERCA2a),⁸¹ yielding larger $I_{Na/Ca}$ and predisposing to delayed afterdepolarizations and triggered arrhythmias.

An increasingly important mechanism of acquired channelopathies is the use of drugs that prolong the QT interval; most are associated with drugs that block I_{Kr} , which is carried by subunits of the human ether-à-go-go (*HERG*) gene.⁸² The list of such drugs is long and includes antiarrhythmic and nonantiarrhythmic drugs. The University of Arizona Health Sciences Center maintains a list of drugs categorized based on their potential to induce torsades de pointes (available at www.crediblemeds.org), including drugs with known risk, drugs with possible risk, drugs with conditional risk, and drugs to avoid in congenital LQTS.

The importance of drug-induced LQTS has mandated pharmaceutical companies to screen early in the process of drug development, mostly for effects on the *HERG* gene product.⁸²

Other Conditions

The QT interval may be prolonged by cocaine abuse, organophosphate compounds, subarachnoid hemorrhage, stroke, myocardial ischemia, fasting using liquid-protein-modified diets, autonomic neuropathy, and human immunodeficiency virus disease.⁸³⁻⁸⁷ Electrolyte abnormalities can not only prolong but also shorten the QT interval. Some of these conditions and others not associated with channelopathies are discussed next.

Electrolyte Abnormalities

Electrolyte abnormalities rarely precipitate but often contribute to ventricular tachyarrhythmias, mostly in relation to abnormalities in serum K^+ , Mg^{2+} , and Ca^{2+} .

Hypokalemia (serum $K^+ < 3.5$ mM) makes the resting membrane potential more negative, rendering cells less excitable and reducing the firing rate of pacemaker cells. Hypokalemia also prolongs the QT interval and flattens the T wave,¹⁰ consequent to a dependency of I_{Kr} conductivity on the square root of extracellular K^+ , resulting in a prolongation of repolarization at lower serum K^+ ; this effect is more pronounced in the mid-myocardial region (greater I_{Kr}/I_{Ks} ratio).

Hyperkalemia (serum K^+ greater than 5.5 mM) makes the resting membrane potential less negative, rendering cells more excitable. By increasing I_{Kr} , hyperkalemia accelerates repolarization and shortens

the action potential, explaining the characteristic peak and tall T-waves. With severe hyperkalemia, the rise rate of phase 0 is reduced, slowing conduction and leading—at very high serum K^+ levels—to widespread blocks (i.e., widened P-waves and widened QRS interval). A very rapid serum K^+ rise can precipitate VF, probably by reentry after developing areas of conduction block.

Mg^{2+} is a cofactor of the Na^+/K^+ pump and hence important for maintaining intracellular K^+ and the resting membrane potential. Mg^{2+} also modulates the effects of various K^+ and Ca^{2+} channels. Hypomagnesemia is associated with QT prolongation and increased risk of ventricular arrhythmias. This effect is usually compounded by other electrolyte deficits including hypokalemia and hypocalcemia.

Serum Ca^{2+} is also important. Hypocalcemia increases the QT interval, predisposing to VT, whereas hypercalcemia exerts the opposite effects reducing the QT interval. Changes in intracellular calcium contribute to arrhythmias associated with acute ischemia and reperfusion and may be important in the genesis of VT induced by exercise and by digitalis.

Hypothermia

Moderate (32°C to 35°C) and severe ($<32^\circ\text{C}$) hypothermia can predispose to ventricular tachyarrhythmias by QT prolongation and QT dispersion.⁸⁹ Typically, patients with hypothermia develop J waves (also known as *Osborn waves*) in the ECG, which reflects accentuation of the inhomogeneity of repolarization caused by the predominant distribution of I_{To} in subepicardial and mid-myocardial regions.⁹⁰

Hypoglycemia

Acute hypoglycemia can trigger VT and VF in patients with diabetes mellitus.⁹¹ The mechanism involves QT prolongation by direct suppression of repolarizing K^+ currents. In addition, the neuroendocrine stress response to hypoglycemia, via release of catecholamines, favors intracellular Ca^{2+} entry and reduction in serum K^+ , further compounding the risk, especially in patients with coronary artery disease, acute myocardial infarction, left ventricular hypertrophy, autonomic neuropathy, congestive heart failure, and in those taking medications that prolong the QT interval.

Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)

ARVC is characterized by progressive replacement of the right ventricular muscle cells by fibrous tissue and fat.⁹² ARVC may be familial with autosomal dominant inheritance.⁹³ Patients present with palpitations and syncope, an important cause of sudden cardiac arrest in subjects younger than 35 years, especially when related to exercise.⁹⁴

The ECG is abnormal in 90% of cases, showing T-wave inversions beyond lead V_1 and epsilon waves in leads V_1 to V_3 . The QRS complex may be widened (>110 milliseconds) with complete or incomplete right bundle branch block morphology. Ventricular premature beats with left bundle branch configuration are present.

CLINICAL DIAGNOSIS

The first element to recognize is wide QRS complexes. They may indicate the origin in ventricular tissue; however, supraventricular ectopic activity can produce wide QRS complexes in the presence of preexistent or rate-dependent bundle branch blocks or aberrant pathways. The diagnostic clue is dissociation from atrial activity; this feature is often difficult to establish, necessitating reliance on other indirect features as discussed later. Ventricular arrhythmias present in several forms.

Premature Ventricular Contractions (PVCs)

PVCs are isolated ventricular ectopic beats. The QRS is typically wide with opposing T-wave polarity and a full compensatory pause. PVCs may present one after each normal QRS in the form of bigemini and also as couplets (two consecutive PVCs).

Ventricular Tachycardia (VT)

VT is defined as three or more consecutive ventricular ectopic beats with a rate typically greater than 100 bpm, often ranging between 130 and 170 bpm. QRS complexes are 120 ms or longer. However, wide QRS complex tachycardias can also be supraventricular when the impulse originates above the bifurcation of the His bundle but is conducted with aberrancy (see later).⁹⁵ VTs are classified as *monomorphic* if all QRS complexes have similar morphology and *polymorphic* if they have variable morphology. VTs are considered *nonsustained* if they last less than 30 seconds and *sustained* if they last 30 seconds or longer.

Nonsustained VTs are rarely symptomatic but are an independent risk factor for sudden cardiac death in patients with severe congestive heart failure.⁹⁶ Most sustained VTs present with palpitations, chest discomfort, and weakness or with more severe symptoms such as dizziness, angina, syncope, seizures, and even sudden cardiac death.

Monomorphic Ventricular Tachycardia

Monomorphic VTs are the most common types of VTs and are usually associated with structural heart disease. The mechanism is commonly reentry operating within or around damaged myocardium. Examination of the jugular veins may show cannon A waves, indicative of AV dissociation.

A standard 12-lead ECG reveals a wide-complex tachycardia with regular complexes of similar morphology. A representative tracing is shown in Figure 80-6. Establishing the diagnosis requires excluding the possibility of supraventricular tachycardia (SVT) with aberrancy. It is appropriate to assume that a wide-complex tachycardia is VT until proven otherwise in patients with myocardial ischemia, heart failure, and hemodynamic instability. SVT with aberrancy should be suspected if there is a history of previous aberrant rhythms, accessory pathways, and baseline or rate-induced bundle branch block. The ECG should be examined for evidence of AV dissociation (i.e., P waves and QRS complexes at uncoupled rates), which is specific for VT. Use of an esophageal lead could be useful by amplifying atrial potentials.

Some special forms of VT tend to be mistaken for SVT with aberrancy.⁹⁷ These include bundle branch reentrant tachycardia, in which the impulse travels down the right bundle branch, across the interventricular septum, and up the left bundle branch.⁹⁸ The morphology resembles SVT with left bundle branch block (LBBB) and is common among patients with nonischemic dilated cardiomyopathy.⁹⁹ Right ventricular outflow tract tachycardia is another condition caused by triggered activity from delayed afterdepolarizations that most commonly originate in the right ventricular outflow tract.¹⁰⁰ The tachycardia usually presents with LBBB morphology and right axis deviation. Right ventricular outflow tract tachycardias occur in structurally normal hearts, typically in young individuals, and are responsive to verapamil

or adenosine.¹⁰¹ Finally, there are fascicular tachycardias that originate from either fascicle of the left bundle branch. They occur in structurally normal hearts, mimic SVT with aberrancy, and are responsive to β -blockers and verapamil.¹⁰²

ECG algorithms are available to help differentiate VT from SVT. A widely accepted four-step algorithm was developed by Brugada et al. in the early nineties and reported to have 98.7% sensitivity and 96.5% specificity for VT.¹⁰³ However, more recent studies found the Brugada criteria to have lower sensitivity and specificity when used by emergency department physicians and cardiologists.¹⁰⁴ Vereckei et al. proposed a simpler criterion based on analysis of aVR and reported greater sensitivity and specificity.¹⁰⁵ The aVR lead is useful because in normal sinus rhythm and in supraventricular tachycardias the ventricular activation wavefront moves away from aVR, typically yielding a QS complex and not an R wave, which is the step one criterion in the new algorithm (Fig. 80-7).

Polymorphic Ventricular Tachycardia

Polymorphic VTs have irregular rhythms, usually compromise hemodynamic function, and may quickly degenerate into VF. Variation in QRS morphology represents changes in the electrical axis. One special form of polymorphic VT is torsades de pointes. This is a descriptive term denoting a rotating electrical axis in 180 degrees along an imaginary axis ("twisting points"); it is typically associated with LQTS. Representative tracings are shown in Figure 80-8.

Accelerated Idioventricular Rhythm (AIVR)

AIVR is a form of automatic ventricular arrhythmia characterized by regularly wide QRS complexes with a rate between 50 and 120 bpm. It is often slightly faster than the underlying sinus rhythm. AIVR does not produce symptoms, and the treatments for VT do not apply.¹⁰⁶ The presence of AIVR may indicate underlying myocardial ischemia.

Ventricular Fibrillation (VF)

VF is recognized by the abrupt onset of irregular waveforms of varying contour, duration, and amplitude without identifiable QRS and T waves accompanied by the inability of the heart to generate blood flow, precipitating unconsciousness within seconds. VTs or SVTs that conduct through accessory pathways (e.g., Wolff-Parkinson-White syndrome) may be the initiating rhythm. Generalized seizures and agonal breathing may follow.

ACUTE MANAGEMENT

PVCs and episodes of nonsustained VT are of little hemodynamic significance in the structurally normal heart and may occur associated with use of stimulants, electrolyte abnormalities, hypoxemia,

FIGURE 80-6 ■ ECG tracing (lead II, III, and V₁) showing couplets followed by an 11-beat episode of nonsustained monomorphic ventricular tachycardia. ECG, electrocardiography.

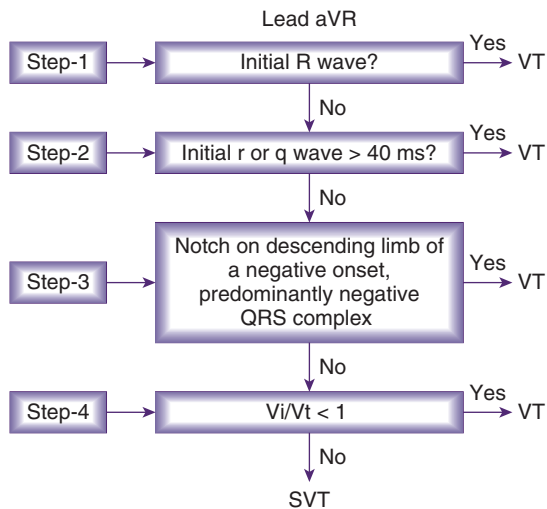

FIGURE 80-7 ■ aVR algorithm for distinguishing wide-complex monomorphic ventricular tachycardia (VT) from supraventricular tachycardia. VT is diagnosed whenever the analysis of aVR yields a positive answer to each successive step. In step 4, Vi and Vt refer to ventricular activation velocity measured as the vertical excursion (in millivolts) during the initial (Vi) and terminal 40 ms (Vt) of the QRS complex. When the initial or terminal 40 ms displays both positive and negative deflections, the sum of their absolute values (disregarding polarity) is used to calculate Vi and Vt, with the Vi/Vt ratio determining whether the rhythm is VT or supraventricular tachycardia. (From Vereckei A, Duray G, Szenasi G, Altemose GT, Miller JM. Application of a new algorithm in the differential diagnosis of wide QRS complex tachycardia. *Eur Heart J* 2007;28:589–600.)

catecholamine discharge, and medications, to name a few conditions. Management should focus on removing contributing factors. The risk of progression to sustained VT is low. Even the notorious R-on-T phenomenon has been shown to be of prognostic significance for the development of VF only in patients with a predisposing substrate such as Brugada syndrome.¹⁰⁷ Antiarrhythmic drugs are typically not required. Persistence of nonsustained VT after an episode of critical illness should prompt assessment of underlying cardiac substrate and possible triggers.

The management of sustained ventricular tachyarrhythmias requires concurrent diagnostic and therapeutic interventions. This requirement is particularly the case in pulseless VT, polymorphic VT, and VF when delivery of unsynchronized electrical shocks and advanced cardiac life support cannot be delayed. In less urgent situations, treatment should focus on identifying the substrate and the triggering events. Arrhythmogenic conditions commonly present in critically ill patients include hemodynamic and respiratory abnormalities, endogenous or exogenous adrenergic states, acid-base and electrolyte imbalances, the presence of proarrhythmic drugs, prolongation of the QT interval, ongoing myocardial ischemia, and mechanical stimulation of cardiac structures. Often, the treatment of these factors suffices to terminate the arrhythmic episode. Specific antiarrhythmic interventions should take into consideration the type of rhythm and the degree of hemodynamic stability.

Ventricular Arrhythmias with Preserved Blood Flow

Monomorphic Ventricular Tachycardia

Direct-current synchronized cardioversion and intravenous antiarrhythmic agents are acceptable first-line options. Antiarrhythmic agents have the advantage of exerting a persistent effect after termination of the event and that anesthetic agents are not required; however,

A

B

FIGURE 80-8 ■ Torsades de pointes. **A**, Patient with a demand ventricular pacemaker developed QT prolongation (≈ 640 milliseconds, seen during paced rhythm) after treatment with amiodarone for recurrent ventricular tachycardia (VT). An episode of torsades de pointes developed that spontaneously terminated with resumption of a paced ventricular rhythm. **B**, Tracing from a young boy with congenital long QT syndrome and marked prolongation of the QTU interval (≈ 600 milliseconds). TU alternans is noted before a late premature complex, occurring on the downslope of the TU wave, initiates an episode of VT. (From Braunwald E, Zipes D, Libby P, editors. *Heart disease: a textbook of cardiovascular medicine*, 6th ed. Philadelphia: Saunders; 2001, p. 868.)

patients may experience adverse effects including hypotension and increased susceptibility to arrhythmias, given that most agents cause QT prolongation.

The American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) 2006 Guidelines for management of patients with ventricular arrhythmias¹⁰⁸ recognize various drugs available in IV formulation for VT, including flecainide, propafenone, sotalol, procainamide, lidocaine, and amiodarone, with availability contingent on the specific country. The same 2006 Guidelines recommend IV procainamide (or ajmaline in some European countries) as a reasonable initial choice for patients with stable sustained monomorphic VT.^{109,110} Close monitoring is recommended, as IV procainamide can cause transient hypotension,¹¹¹ especially in patients with severe left ventricular dysfunction. For patients with sustained monomorphic VT who are hemodynamically unstable, are refractory to electrical shocks, or have recurrent episodes despite procainamide or other agents, IV amiodarone is considered a reasonable choice.^{112,113} The initial effect of amiodarone is to slow down AV nodal conduction and block adrenergic stimulation. However, effects

on ventricular conduction and refractoriness develop more gradually, achieving the maximal effect only after weeks or months of treatment.^{114,115}

When sustained monomorphic VTs are associated with an acute ischemic substrate (i.e., unstable angina or myocardial infarction), lidocaine is considered a reasonable initial choice.¹¹⁶ Calcium channel blockers such as verapamil and diltiazem should not be used to terminate wide-QRS-complex tachycardia of unknown origin, especially when myocardial dysfunction is present.

Addition of a second antiarrhythmic agent is discouraged to avoid compounding proarrhythmic effects. Thus, a single agent should be used, followed by direct-current synchronized electrical cardioversion if optimal dosing fails.

Direct-current synchronized cardioversion should be considered first-line treatment in patients who are unstable or in those with borderline blood pressure who could experience further deterioration by the vasodilator and antiinotropic effects of antiarrhythmic agents. Monophasic waveform electric shocks at an initial energy of 100 J or higher are effective with comparable or lower energy levels expected to be effective using biphasic waveform electric shocks. Transvenous pacing with override pacing can terminate monomorphic VT and should be considered in instances of failed cardioversion or frequent recurrence despite antiarrhythmic medication.

Ventricular Arrhythmias with Cessation of Effective Blood Flow

Cessation of blood flow occurs with pulseless VT, VF, and polymorphic VT. The immediate priority is to reestablish an organized electrical activity with mechanically competent pump function, typically requiring the unsynchronized delivery of electric shocks with cardiopulmonary resuscitation contingent on the duration of the arrhythmia and the response to electrical shocks.

Ventricular Fibrillation and Pulseless Ventricular Tachycardia

Current resuscitation algorithms¹¹⁷ consider VF and pulseless VT as rhythms requiring delivery of electric shocks upon their recognition through an automated external defibrillator or through manual defibrillators along with quality chest compressions. If VT/VF persists after the third shock, IV amiodarone is recommended. The energy level of the initial electric shock depends on the specific device. For biphasic waveform defibrillators, the energy level typically ranges from 150 to 200 J. Equal or higher energy levels are recommended for the second and subsequent shocks. If the available defibrillator uses monophasic waveforms, the energy level should be 360 J for all shocks. The probability of survival after VF and pulseless VT is inversely related to the time elapsed between the onset of the arrhythmia and the delivery of electric shocks.¹¹⁸

Electrical storm is a rather uncommon but highly lethal phenomenon defined as recurrent episodes of VF, occurring mainly in the course of an acute myocardial infarction. Conventional antiarrhythmic drug therapy—including lidocaine and procainamide—often fails to secure a stable sinus rhythm.

Polymorphic Ventricular Tachycardia

Polymorphic VT with cessation of effective blood flow is treated as VF with unsynchronized shocks at the same energy as for VF. As with all ventricular arrhythmias, substantial effort must be directed at identifying and correcting the causes.

Polymorphic VT with a normal QT interval is most frequently associated with acute myocardial ischemia but also with cardiomyopathies,

idiopathic polymorphic VT, and catecholaminergic VT. In this setting, use of IV beta-blockers¹¹⁹ or IV amiodarone¹²⁰ is effective. Coronary angiography should be considered for recurrent polymorphic VT when ischemia is suspected.¹²¹

Polymorphic VT with prolonged QT interval is usually associated with bradycardia. The management includes discontinuation of drugs that prolong the QT interval, correction of electrolyte abnormalities, and avoidance of catecholamines. In the setting of congenital LQTS, beta-blockers (or sympathetic interruption), pacing, and implantation of an internal cardioverter defibrillator device should be considered. In the acquired forms of LQTS, IV magnesium, overdrive pacing, and beta-blockers after pacing are recommended interventions.

CONCLUSION

Ventricular tachyarrhythmias are important and common manifestations of cardiac and extracardiac abnormalities in critically ill patients. In addition to the traditional assessment based on ECGs and hemodynamic manifestations, understanding and recognition of the processes that affect ion channels, pumps, exchangers, and signaling mechanisms are important for proper management. Awareness of prevalent, clinically relevant, mutations that affect cardiac channels has increased. The intensivist should be alert and prepared to identify these conditions and provide the necessary initial treatment and referral when appropriate. Initial enthusiasm for antiarrhythmic agents has diminished as the proarrhythmic effects of various compounds have become evident. Some drugs are no longer recommended as first-line agents, whereas others have become components of accepted algorithms. More emphasis is currently being placed on understanding arrhythmogenic mechanisms and on correcting the precipitating and maintaining factors.

KEY POINTS

1. Hereditary and acquired abnormalities in cardiac ion channels can alter the action potential, mostly by prolonging repolarization, and predispose to ventricular tachyarrhythmias, especially *torsades de pointes*.
2. Ventricular arrhythmias are the result of abnormalities in impulse generation (automaticity and triggered activity) and impulse conduction (reentry).
3. Proper management of ventricular tachyarrhythmias requires assessment of precipitating and maintaining conditions; often, the removal of these conditions is all that is needed.
4. A long QT interval in the baseline electrocardiogram should prompt a diligent search for possible drugs, metabolic abnormalities, or hereditary channelopathy.
5. Ventricular tachyarrhythmias in critically ill patients are often precipitated by cardiac, metabolic, and respiratory processes.
6. AV dissociation is a reliable sign that a wide-complex tachycardia is ventricular; this may be evident on the surface 12-lead ECG or after analyzing an esophageal lead.
7. Direct-current synchronized cardioversion should be considered first-line treatment in patients with VT who are hemodynamically unstable or have heart failure.

■ CONDUCTION DISTURBANCES

Bradyarrhythmias and conduction blocks are common in the intensive care unit (ICU). A broad range of clinical presentations and pathologic findings occurs in this group of arrhythmias. Some bradyarrhythmias are benign and asymptomatic and do not require treatment. Other atrioventricular (AV) blocks and arrhythmias are life threatening and warrant immediate intervention.

Normal Cardiac Conduction

Normal depolarization and impulse conduction are central to maintaining cardiac output. Two types of cells are found in the heart: (1) cells responsible for impulse generation and conduction, and (2) cells responsible for contraction. Depolarization of the myocardium begins in the sinoatrial (SA) node. The SA node is located in the posterior and superior portion of the right atrium and is innervated by the sympathetic and parasympathetic nervous systems.

The impulse is generated by a specialized group of cells with the ability to depolarize spontaneously. Initial depolarization of the SA node is not seen on the electrocardiogram (ECG). The P wave is generated when the impulse spreads throughout the atria. There is no specific conduction system in the atria to convey the SA node impulse to the AV node.¹ The impulse is transmitted by depolarization of adjacent atrial myofibrils. Approximately halfway through the P wave, the impulse reaches the AV node. The second half of the P wave is due to left atrial depolarization.

In a normal heart, the atria and ventricles are electrically isolated from each other except at the AV node. The AV node is located in the atrial septum near the apex of the triangle of Koch. The AV node is innervated by the sympathetic and parasympathetic nervous systems. Conduction through the AV node accounts for the majority of the PR interval. After emerging from the AV node, the impulse is conducted through the bundle of His. From there, the impulse travels down the right and left bundle branches and their fascicles to the Purkinje network, which causes ventricular contraction.

Failure of Impulse Conduction

Failure of conduction can occur anywhere along the conduction pathway. AV node block is most often caused by medications, increased parasympathetic tone, or ischemia. AV node blocks are usually reversible, except when infarction permanently damages a portion of the conduction pathway. Infranodal blocks are rarely caused by physiologic abnormalities. Structural heart disease and anatomic disruption of the conduction system are the main causes of infranodal heart block. Rare causes of infranodal block include disruption of the bundle of His from aortic valve calcification, Lenègre's disease (idiopathic degeneration of Purkinje fibers), and Chagas' disease.²

Once AV block is identified, it is helpful to determine the site of conduction pathology. The anatomic site can be identified in most cases by synthesizing the type of AV block, the width of the QRS complex, and the QRS morphology. When the QRS complex is narrow (<120 milliseconds), the site of pathology is most likely supraventricular. When the QRS complex is wide, the most likely site of AV block is infranodal. Bundle branch and fascicular blocks produce various QRS

morphologies that may aid in determining the specific anatomic location of the pathology.

Clinical Presentation

Syncope and presyncope are the most dramatic symptoms of conduction disturbances; palpitations, dyspnea, angina, and fatigue are seen as well. Many patients are asymptomatic. A significant number of patients develop bradydysrhythmias after an acute myocardial infarction (MI) (Table 81-1).³

Diagnostic Evaluation

A high-quality ECG is paramount for the appropriate evaluation of P waves and various intervals. Routine monitoring in the ICU is usually accomplished with a single- or three-lead display at the bedside. The lead chosen should clearly delineate the P waves and QRS complexes. Complex arrhythmias may require Lewis leads, intraatrial leads, or esophageal ECG monitoring. Calipers significantly aid in the diagnosis of AV blocks and are helpful to "march out" P waves and intervals. Holter or continuous loop monitoring can also be an important tool in the evaluation of AV block.⁴ These monitors allow one to evaluate the cardiac conduction system during a patient's activities of daily living. A monitoring period of at least 24 hours is recommended, so that both daytime and nighttime activities are included.

Sinus Node Abnormalities

Sinus Bradycardia

Sinus bradycardia is defined as a sinus rhythm with a heart rate less than 60 beats per minute. Sinus bradycardia is divided into two categories: appropriate and inappropriate. Appropriate bradycardia is seen in young, healthy individuals and endurance athletes; the heart rate increases appropriately with exercise. Pathologic sinus bradycardia does not increase appropriately with exercise. Medications are the most common cause of inappropriate sinus bradycardia; autonomic influences, electrolyte abnormalities, and intrinsic structural disorders are others. In older individuals, sinus bradycardia can result from a decrease in the sinus node firing rate, which is a normal part of the aging process. Ischemia may also increase vagal tone and result in a slower heart rate.

Sinus Arrest

Sinus arrest occurs when the pacemaker cells in the SA node fail to depolarize. Pauses of less than 3 seconds may be seen in up to 11% of normal individuals and should not cause concern.⁵ There is a higher incidence of sinus pause in athletes. Pauses longer than 3 seconds are usually considered pathologic and should be evaluated.

SA exit block and sinus arrest appear similar on ECGs, but they should be distinguished, if possible. The duration of the pause in exit block is a multiple of the P-P interval. High-grade exit block cannot be distinguished from sinus arrest. The treatment is the same for both conditions.⁶

Noninvasive testing includes ECG, carotid sinus massage, and a tilt table test. Carotid sinus massage is useful to diagnose carotid sinus hypersensitivity. Risks of carotid sinus massage include transient ischemic attack and stroke, and the test should not be performed on patients with carotid bruits. The tilt table test is helpful to determine whether

TABLE 81-1

Incidence of Bradydysrhythmias in Acute Myocardial Infarction

| RHYTHM | INCIDENCE (%) |
|---------------------------------|---------------|
| Any bradydysrhythmia | 25-30 |
| Sinus bradycardia | 25 |
| Junctional escape rhythm | 20 |
| Idioventricular escape rhythm | 15 |
| First-degree AV node block | 15 |
| Second-degree AV block type I | 12 |
| Second-degree AV block type II | 4 |
| Third-degree block | 15 |
| Right bundle branch block | 7 |
| Left bundle branch block | 5 |
| Left anterior fascicular block | 8 |
| Left posterior fascicular block | 0.5 |

AV, atrioventricular.

syncopal episodes are due to autonomic dysfunction. Invasive diagnostic testing of the SA node can also be performed, although this is rarely necessary.

The treatment of sinus node dysfunction can be temporary or permanent. Atropine or an isoproterenol drip can be used in the ICU as a bridge to permanent pacemaker placement. Temporary pacing is indicated for patients who fail to respond to medical therapy.

Carotid Sinus Hypersensitivity

Carotid sinus hypersensitivity is diagnosed when ventricular asystole greater than 3 seconds' duration (usually due to a sinus pause or arrest) or a drop in systolic blood pressure greater than 50 mm Hg occurs in response to carotid massage. If symptoms occur, a 30 mm Hg drop in systolic blood pressure defines a positive response. Treatment is permanent pacing in symptomatic patients only.⁷

Postsurgical Bradydysrhythmias

Bradyarrhythmias are common after cardiac surgery. Valve surgery and septal myectomy can cause significant damage to the conduction system. Prolonged ischemia during heart transplantation may also result in sinus node or conduction system damage. The decision to place a permanent pacer should not be made until 5 to 7 days postoperatively, however, because the bradyarrhythmia may be temporary. Medication administered during surgery or reversible ischemia is often implicated. Permanent pacing is required in 3.2% to 8.5% of patients after valve surgery and approximately 10% of patients after heart transplantation.⁸

Atrioventricular Node Dysfunction

There are many causes and several manifestations of AV node dysfunction. Box 81-1 lists the causes of AV node abnormalities.

First-Degree Atrioventricular Block

First-degree AV block is characterized by a prolonged PR interval greater than 200 milliseconds in adults and 180 milliseconds in children who are not taking medications that can prolong the PR interval (Fig. 81-1). All of the P waves are conducted to the ventricles, and the PR interval is typically fixed. Potential causes of first-degree AV block include delayed conduction through the atria from the SA node to the AV node, a delay in AV node conduction, or prolonged infranodal conduction.

BOX 81-1

Causes of Atrioventricular Node Dysfunction

Drugs
 Digoxin
 Beta-blockers
 Certain calcium channel blockers
 Membrane-active antidysrhythmic drugs
 Primary cardiac disease
 Ischemic heart disease
 Idiopathic fibrosis of the conduction system
 Congenital heart disease
 Calcific valvular disease
 Cardiomyopathy
 Metabolic
 Hyperkalemia

FIGURE 81-1 ■ Electrocardiogram from a patient with first-degree atrioventricular block. The PR interval is approximately 290 milliseconds. All P waves are being conducted to the ventricles. The PR interval is constant.

Conduction delays from the SA node to the AV node are typically due to structural causes, such as right atrial enlargement or an ostium primum atrial septal defect. A delay in AV node impulse conduction is the most common cause of first-degree AV block. Patients with delayed conduction in the AV node often have a PR interval greater than 300 milliseconds. Infranodal causes of first-degree AV block are rare and are typically associated with a wide QRS complex due to disease in the fascicles or the bundle of His. First-degree AV block can also occur when each of these conduction times is at the upper limit of normal and summate to produce an overall prolongation of the PR interval.⁷

First-degree AV block is typically benign and asymptomatic. It can be seen in 0.5% of young adults without heart disease. In older people, first-degree block is most often the result of idiopathic degenerative disease. A prolonged PR interval is often an incidental finding when an ECG is ordered for other reasons. It rarely warrants further workup or treatment.

Second-Degree Atrioventricular Block Type I

Second-degree AV block type I, or a Wenckebach (or Mobitz type I) rhythm, is defined by a progressive prolongation of the PR interval with each successive beat, with eventual failure of a P wave to conduct

FIGURE 81-2 ■ Electrocardiogram rhythm strip from a patient with second-degree atrioventricular block type I. Note progressive prolongation of the PR interval until failure of conduction occurs. Also note the reciprocal RP shortening. The pattern of conduction is 3:2.

to the ventricles (Fig. 81-2). This results in a dropped beat and failure of the ventricles to depolarize. The P waves occur at regular intervals. As the PR interval lengthens, the RR interval becomes shorter, which eventually results in decremental conduction. There is a reciprocal relationship between the RP interval and the PR interval.

The pathophysiology of second-degree AV block type I is similar to that of first-degree AV block, except that intraatrial block is usually not a cause. For all practical purposes, second-degree AV block type I is caused by a block in AV node conduction. The QRS complex is generally narrow.

QRS complexes are typically grouped in twos, threes, fours, and so on. Group beating is characteristic of Wenckebach rhythms. The rhythm is described by recording the number of P waves and QRS complexes involved in the pattern of block (e.g., 4:3 or 3:2). During a dropped beat, a P wave is observed with no corresponding QRS complex. Second-degree AV block type I is a stable rhythm and has a much better prognosis than does a Mobitz type II rhythm. If the Wenckebach rhythm is due to medication, resolution of the block can be monitored with an ECG. Once the medication is discontinued, a shortening of the PR interval and a lengthening of the RP interval, with a corresponding improvement in AV node conduction, may be observed.

Second-Degree Atrioventricular Block Type II

Second-degree AV block type II (or Mobitz type II block) is characterized by a sudden nonconducted P wave without a change in the PR interval. A P wave with no corresponding QRS complex is observed on the ECG (Fig. 81-3). This is an inherently unstable rhythm, and serious pathology may be present. In contrast to the Mobitz type I rhythm, type II is described as a high degree of AV block, with P wave-to-QRS ratios of 3:1 or 4:1. A Mobitz type II rhythm is almost always due to an infranodal conduction disturbance. The conducted QRS complexes are often wide, and a bundle branch block pattern is often observed. Second-degree AV block can result from an anterior wall MI. Type II second-degree AV block can progress to complete heart block.

2:1 Atrioventricular Block

When conduction of every other P wave is blocked, 2:1 AV block is present. The PR interval of the conducted beat remains fixed. QRS complexes are regular and occur at half the atrial rate. A 2:1 AV block can be caused by a Mobitz I (usually with a narrow QRS complex) or Mobitz II (with a wide QRS complex) rhythm, and the two entities are difficult to distinguish.

Third-Degree Atrioventricular Block

Third-degree AV block is characterized by complete AV dissociation. There is no conduction of the atrial signal through to the ventricle, so the atrial and ventricular systems operate independently. On an ECG, the P waves “march through” and are not associated with ventricular contraction. The PR intervals are irregular. The ventricular complexes may be junctional (narrow QRS complex; rate, 40–60 beats per minute) or ventricular (wide QRS complex; rate, <40 beats per minute). Depending on the escape heart rate, patients may present with tachypnea, dyspnea on exertion, fatigue, cyanosis, or syncope (Fig. 81-4).

FIGURE 81-3 ■ Electrocardiogram demonstrating second-degree atrioventricular block type II. The PR interval is constant before and after the blocked P waves. The QRS complex is widened.

FIGURE 81-4 ■ Complete heart block. The PR intervals are irregular because the ventricles and atria represent two independent sources of depolarization.

Third-degree block can be divided into congenital and acquired causes. Sixty percent of patients with congenital heart block are female. Patients with congenital third-degree block often have an escape rhythm with an adequate rate.⁹ Acquired third-degree block occurs most frequently in the seventh decade of life and usually requires permanent pacing; these patients are often male. Specific causes include medications, ischemia, progression from Mobitz type II rhythm, and infarction. Acute MI results in third-degree heart block in 14% of patients with inferior wall infarcts and 2% of patients with anterior infarcts. Third-degree block is usually observed within 24 hours after an MI. Third-degree block as a complication of an inferior MI is usually temporary and may require only temporary pacing. Complete heart block as a result of an anterior MI usually requires a permanent pacer.

Treatment involves correction of underlying disorders and immediate transcutaneous or transvenous pacing in unstable patients. If the primary cause cannot be medically managed, permanent pacing is required.

Diagnostic Pitfalls

Determining the degree of AV node block is usually straightforward if an adequate ECG has been obtained. There are circumstances, however, in which one may be misled to an incorrect diagnosis.

Third-degree block is occasionally misdiagnosed as second-degree block type II if there appears to be a constant PR interval. This may occur for short periods on an isolated rhythm strip. The clinician must, therefore, examine a strip for an appropriate length of time to make the correct diagnosis. Vagal maneuvers can also be attempted and may identify a second-degree AV block that is really a third-degree AV block.

With isorhythmic AV dissociation, the P waves and QRS complexes occur at a similar rate. The P waves may never “march out” long enough to determine whether they are all conducting. Interventions such as vagal maneuvers to change the P to QRS relationship may aid in diagnosis.

When second-degree AV block is fixed (2:1, 3:1, 4:1), some P waves may be concealed during the repolarization phase of the ECG. This may occur in an acute MI or with ischemia. Vagal maneuvers and examination of multiple leads may be necessary to correctly identify the AV block.

When complete AV dissociation occurs with accelerated junctional or ventricular rhythms, it is possible that some of the atrial impulses would be conducted if the heart rate were slower. It is best to designate these rhythms as complex AV dissociation.

Therapy

Medical therapy for AV block consists of atropine, adrenergic agents, digoxin immune Fab (if appropriate), and pacing. Atropine decreases

vagal tone and is useful for hypervagotonia but not AV node ischemia. It is more useful in inferior wall MI than in anterior wall MI. Atropine will not improve third-degree AV block or a Mobitz type II block if the pathology is below the AV node, and it is ineffective in heart transplant patients. Atropine should be used with caution in patients with Mobitz type II rhythms because a paradoxical decrease in heart rate can occur.

Digoxin immune Fab should be used in symptomatic patients with digoxin-induced AV block. The number of vials required is approximately equal to the patient's weight (in kilograms) times the digoxin serum level (in ng/mL), divided by 100.

PACEMAKERS

Although pacemakers are reliable, patients occasionally present with abnormalities in one or more pacemaker functions that may impact their current illnesses. Intensivists can expect to routinely encounter patients with pacemakers, and it is helpful to be familiar with the basics of their functions and malfunctions.

The North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group created a code consisting of five letters to describe pacemaker functions, known as the NBG pacemaker code (Table 81-2).¹⁰ The first three letters describe the antibradycardia functions, the fourth describes the programmability of rate responsiveness, and the fifth describes any antitachycardia functions. A pacemaker may carry one classification (e.g., DDD) but be capable of several modes of function, depending on how it is programmed. Indications for permanent pacing were updated by the American College of Cardiology in 2002.¹¹

The pacemaker itself consists of two components: a pulse generator and wire leads connecting the generator to the heart. The pulse generator consists of a lithium-based battery and the circuitry to detect and analyze the cardiac rhythm and produce the output. The battery can last more than 10 years, depending on the type of programming; at the end of its life, it produces a gradual rate decrease, not an abrupt drop-off.¹²

Pacemakers also contain a reed switch that can be used to assess the pacemaker's pacing ability. When an external magnet is placed over the pulse generator, the reed switch closes, disabling the sensing mechanism. The unit then fires asynchronously without regard for the patient's underlying rhythm. The pacing rate is unique to each model and manufacturer, and the magnet-programmed rate can vary depending on whether the battery is at the beginning or end of its life or at a time of elective replacement.

Each patient is given a card when a pacemaker is implanted that describes the manufacturer, model, and pacing parameters. The pacemaker itself also contains a radiopaque code, visible on x-ray, that identifies the unit. Pacemakers can be interrogated with a manufacturer-specific program that retrieves ECG information about the unit, which can help assess its functioning. An electrophysiologist should be consulted when a malfunction is suspected.

Two types of lead systems exist: unipolar and bipolar. Bipolar leads are considered standard unless patient-specific factors warrant the use of a unipolar lead. Unipolar programming uses the lead in the endocardium as the cathode and the pacemaker unit itself as the anode.

Because voltage in a unipolar lead is detected over a greater distance, the pacing spike is larger than with bipolar lead programming. Leads can be attached to the endocardium by active fixation (screwed into the myocardium) or passive fixation (held in place by fins). Passive fixation is associated with a greater incidence of dislodgment and perforation.¹³

Assessment of pacemaker function requires knowledge of its parameters. A pacing spike must be present on the ECG to properly evaluate the unit. If one is not present, a magnet can be placed over it and an ECG recorded. This can then be used, in combination with the clinical situation and prior ECGs, to determine the pacemaker's function.

Every pacemaker is programmed to fire after a maximum period in which no activity has been detected. This is called the *lower rate-limiting interval*, and it is the time between two consecutive paced beats. The *escape interval* is the time between a native complex and the following pacemaker spike. A slight delay beyond the lower rate-limiting interval can be programmed into the pacemaker when it senses a native QRS complex. This is an attempt to permit the heart to generate its own output and thus function in a more physiologic manner; this is called *rate hysteresis*, and it is found most often in ventricular demand pacemakers.¹⁴ Dual-chamber pacers have an interval programmed between atrial and ventricular spikes called the *AV interval*, which functions basically as the PR interval. The interval between a ventricular spike and the next atrial pacing spike is the *ventriculoatrial interval*. The AV and ventriculoatrial intervals sum to equal the lower rate-limiting interval.

Complications

Failure to Sense (Undersensing)

Undersensing occurs when the pacemaker generates output regardless of the patient's underlying rhythm (Fig. 81-5). A spike is seen at an interval earlier than the lower rate-limiting interval. Pacemaker output then competes with the patient's own intrinsic rhythm. Although ventricular pacing can present a problem when the threshold for ventricular capture has been altered (e.g., by ischemia), and atrial pacing can produce atrial fibrillation, these are rarely urgent problems.¹⁵

Specific causes of failure to sense are listed in Table 81-3. Blanking is not a true cause; rather, it is an instance of functional undersensing

FIGURE 81-5 ■ Failure to sense. Atrial and ventricular pacing spikes are seen around the intrinsic QRS complexes. Pacemaker activity does not lead to capture.

TABLE 81-2 NBG Pacemaker Code

| POSITION | I | II | III | IV | V |

TABLE 81-3 Causes of Pacemaker Undersensing

| CAUSE | TREATMENT |
|---|--|
| Lead fracture | Replace lead |
| Lead dislodgment | Reposition lead or increase sensitivity |
| Insulation defect in pacing lead | Replace lead |
| Magnet interrogation | Remove magnet |
| Blanking | Decrease ventricular refractory period |
| Amplitude of P wave or QRS complex too low to be sensed | Increase sensitivity |
| Myocardial fibrosis | Increase sensitivity or reposition lead |
| Myocardial perforation | Increase sensitivity or reposition lead |
| End of battery life | Replace battery |
| Acute myocardial infarction | Treat myocardial infarction |
| Electrolyte disturbance | Correct electrolytes |
| Antidysrhythmic drugs | Increase sensitivity, change drug |
| Magnetic resonance imaging | Reprogram to VOO, AOO, or DOO mode |
| Defibrillation | Place defibrillator pads as far from pacemaker unit as possible, place in anteroposterior position |
| Complexes occurring in pacemaker's refractory period | None, or use new generator with shorter refractory period |

**FIGURE 81-6** ■ Failure to pace. An unduly long interval passes after the third QRS complex before another beat occurs. The pacemaker should have fired before this intrinsic beat.

in dual-chamber pacemakers. To prevent pacemaker-induced tachycardia, a 12- to 125-millisecond period of inactivity is programmed into the ventricular component after an atrial complex. If an intrinsic QRS complex occurs during this period, it will not be sensed. Scar tissue does not conduct impulses as easily as normal myocardium does, so sensing may not occur. Most pulse generators begin asynchronous pacing at a critical point at the end of their life and will not sense intrinsic activity. Defibrillation can damage the unit; placing the defibrillator pad in an anteroposterior position may help avoid this. The unit should be observed closely after shocks are delivered.

Failure to Pace (Generate Output)

This complication is noted when a pacemaker spike is not seen after the lower rate-limiting interval has been exceeded (except when hysteresis has been programmed; Fig. 81-6). Oversensing occurs when stimuli are erroneously sensed as pacemaker output. As a result, the expected proper output is inhibited; this can be continuous or intermittent. Failure to pace can be a devastating complication for a pacemaker-dependent patient. It is important to determine whether output is truly occurring or not. A 12-lead ECG should be done because spikes may be too small to be seen in a specific lead. Several causes are possible (Table 81-4).

Cross-talk is not a true malfunction of the pacemaker, but it can lead to inhibition of activity. In a dual-chamber system, the output of

TABLE 81-4 Causes of Failure to Pace

| CAUSE | TREATMENT |
|---|---|
| Lead fracture, loose connection, or insulation defect | Adjust or replace leads |
| Battery depletion | Replace battery |
| Pulse generator failure | Replace pulse generator |
| Cross-talk | Program a blanking period or safety pacing |
| Electromagnetic oversensing: | |
| Sensing P or T or U waves | Decrease sensitivity or advance tip deeper into right ventricle |
| Myopotential sensing | Decrease sensitivity or use bipolar sensing |
| Electrocautery | Decrease sensitivity or electrically isolate patient |
| Extracorporeal shock-wave lithotripsy | Decrease sensitivity or use minimal equipment necessary |
| Transcutaneous electrical nerve stimulator (TENS) | Decrease sensitivity, stop TENS unit |
| Magnetic resonance imaging | Program to DOO, VOO, or AOO mode |

**FIGURE 81-7** ■ Failure to capture. After the first QRS complex, a small pacemaker spike occurs that does not result in depolarization of the ventricles. A nonconducted P wave follows, and then a pacemaker spike with capture occurs.

one chamber is sensed as the output of the other, and no pacemaker spike is generated; this occurs more often in unipolar leads. This problem is corrected by programming a blanking period. For a brief period after the atrial output (12 to 25 milliseconds), the ventricular component is inhibited from firing. A second protection against cross-talk is to program the unit to fire depending on when in the AV interval the stimulus is detected. If it occurs immediately after the blanking period, a “safety” spike is generated because it is assumed that it is impossible to differentiate cross-talk from a native QRS complex.

Failure to Capture

This complication occurs when a pacemaker fires as expected but fails to depolarize the myocardium. A pacer spike is seen on the ECG, but no QRS complex immediately follows it (Fig. 81-7). This can be dangerous for a pacemaker-dependent patient and may require temporary pacing until the problem is fixed. Most cases are due to problems with the lead/tissue interface, although isolated problems in the leads or the myocardium can also occur (Table 81-5).^{13,16}

When a lead is placed into the myocardium, tissue fibrosis occurs over the first 4 to 6 weeks. Because scar tissue does not conduct as well as normal myocardium, the output voltage may need to be increased. Twiddler's syndrome is seen when a patient fidgets with the generator and ends up pulling the leads from their attachments to the myocardium. It is confirmed by chest x-ray. The pacemaker is replaced and fixed tightly to the underlying fascia. Perforation of the ventricle typically occurs shortly after the leads are placed and is confirmed by a chest x-ray showing the tip of the lead outside the heart. It is suggested by a change in pacing to a right bundle branch pattern, failure to

TABLE 81-5 Causes of Failure to Capture

| CAUSE | TREATMENT |
|---|---|
| Lead dislodgment from endocardial surface | Repair lead |
| Twiddler's syndrome | Fix unit to chest wall |
| Lead fracture or break in insulation | Replace lead |
| Improperly or inadequately programmed voltage | Reprogram voltage |
| Battery failure | Replace battery |
| Cardiac perforation | Reposition lead (in operating room) or increase voltage |
| Increased threshold for capture Fibrosis or scar tissue at contact site Myocardial ischemia | Increase voltage or reposition lead Treat ischemia |
| Metabolic Hyperkalemia Hypercarbia Hypoxemia Hypothyroidism | Treat abnormality |
| Drugs Beta-blockers Class Ia antidysrhythmics Verapamil Flecainide | Remove drug and replace with another |

capture, contraction of the diaphragm or intercostal muscles with pacing, or development of a pericardial friction rub. Provided the patient is not anticoagulated, the perforation is usually well tolerated.¹⁴ Echocardiography can assess for the presence of a pericardial effusion or tamponade. Repositioning of the lead is typically performed in the operating room after any coagulopathy (if present) has been reversed. An increased threshold for capture can also be caused by myocardial ischemia, metabolic abnormalities, or certain drugs. Definitive treatment involves correcting the underlying disorder.

When assessing for failure to capture, a distinction must be made between pseudofusion and fusion beats. A pseudofusion beat occurs when the pacemaker fires at the same time that an intrinsic beat occurs. The pacemaker output does not depolarize the myocardium, and instead, the pacemaker spike simply deforms the native QRS complex. It is an example of failure to capture. A fusion beat occurs when both the native complex and the pacemaker spike depolarize the myocardium, resulting in a QRS complex that is a hybrid of the two.

Other Problems

Pacemaker-mediated tachycardia, also called *endless loop* or *pacemaker reentrant tachycardia*, is a complication of dual-chamber units. A premature atrial contraction or premature ventricular contraction that travels in a retrograde manner into the atria is sensed by the atrial component of the pacemaker, which induces the ventricular component to fire. The resulting ventricular depolarization reenters the atria, and the cycle continues. An upper rate limit is programmed into the pacemaker, so the tachycardia will not exceed this rate. A tachycardia paced by atrial and ventricular spikes is seen. Application of a magnet terminates the dysrhythmia; adenosine may not reliably block it.¹⁷ A blanking period must be programmed.

Pacemaker syndrome is seen when only the ventricle is paced. Patients present with lethargy, syncope, dizziness, weakness, fatigue, palpitations, or congestive heart failure. It occurs because of an inability to raise the heart rate with exercise and because of the loss of AV synchrony. Dual chamber pacing is required to correct this.

The diagnosis of an MI in a patient with a functioning pacemaker is difficult. Criteria similar to those in patients with left bundle

BOX 81-2 Indications for Temporary Cardiac Pacing

Drug toxicity
Beta-blocker
Calcium channel blocker
Digitalis-induced dysrhythmia (when direct current cardioversion is contraindicated)
Hyperkalemia with bradycardia or asystole
Hypothermia (transcutaneous pacing only)
Symptomatic bradycardia (including hemodynamic compromise, syncope, or ventricular ectopy in response to bradycardia) not responsive to atropine
Pacemaker malfunction with symptoms
Alternating BBB (after MI)
RBBB with alternating LAFB or LPFB (after MI, not known to be old)
RBBB with LAFB or LPFB, or LBBB with first-degree heart block, not known to be old
Mobitz type II heart block
Asystole
LBBB not known to be old
Recurrent sinus pauses >3 seconds not responsive to atropine
RBBB with first-degree heart block
Possibly helpful: bifascicular block or RBBB of unknown age

BBB, bundle branch block; LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; MI, myocardial infarction; RBBB, right bundle branch block.

branch block have been proposed, but sensitivity and specificity are lower.¹⁵

Advanced Cardiac Life Support protocols are not contraindicated by the presence of a pacemaker. Defibrillator pads should be kept as far away from the pulse generator as possible to minimize any damage to the unit.

Examination by magnetic resonance imaging has been considered contraindicated because of the interaction between the strong magnetic field and the pulse generator. Increased pacing rates, decreased rates, and pacing at the magnet rate have all been seen. However, programming the pacemaker to an asynchronous mode (AOO, VOO, or DOO) and close monitoring of the patient, along with the use of lower magnetic fields, may allow safe imaging.¹⁸

TEMPORARY PACING

Temporary cardiac pacing may be required for emergent or elective reasons. In general, any patient with bradycardia causing symptoms or hemodynamic instability that is unresponsive to atropine ought to be considered for temporary pacing (Box 81-2).¹⁹ In most cases, this occurs after an acute MI,¹⁹ but certain drug poisonings may benefit from pacing,^{20,21} and some interventions may, because of underlying disease, predispose a patient to significant bradycardia.

Modes of Pacing

Several modes of temporary pacing are available. Transcutaneous pacing involves placing the pacing pads on either the chest wall and back (the usual locations) or in an anterolateral position (especially if external defibrillation may be required). The negative electrode is placed over the apex of the heart. This is the easiest mode to use, but it is uncomfortable for a conscious patient and may require analgesia or sedation.

Transvenous pacing is usually well tolerated by patients but requires a high degree of skill to correctly place the pacing electrode in the right ventricle. Therefore, the American College of Physicians and the American College of Cardiology recommend that only physicians formally trained in their use place these electrodes.²² The right internal jugular vein approach is best because of its more direct route to the heart; the left subclavian vein approach can also be used but should be avoided, if possible, because it is a preferred site for placement of a permanent pacemaker.¹⁹

Transesophageal pacing allows pacing of either the atria or the ventricles, but it is not a commonly used modality. Transthoracic pacing, in which leads are placed percutaneously into the ventricular myocardium, is also possible but is fraught with complications, including pericardial tamponade, pneumothorax, visceral injury, and coronary artery laceration.

Pacing leads placed during open heart surgery can also be used.

When establishing temporary pacing, the pacing threshold should be determined, and the pacing energy should then be set at two to three times this minimum output. Thresholds should be checked daily.

KEY POINTS

Conduction Disturbances

1. Atrioventricular (AV) node block is most often caused by medications, increased parasympathetic tone, or ischemia. Except when infarction permanently damages a portion of the conduction pathway, such blocks are usually reversible. Infranodal blocks, however, are rarely caused by physiologic abnormalities.
2. First-degree AV node block and Wenckebach block typically do not require treatment. Type II second-degree heart block and complete heart block usually do require treatment.
3. Therapy for AV block consists of atropine, adrenergic agents, digoxin immune Fab (if appropriate), and pacing.
4. Bradyarrhythmias are common after cardiac surgery and may require temporary pacing, but a decision to place a permanent pacemaker should not be made until 5 to 7 days after surgery.

Pacemakers

1. A cardiologist or electrophysiologist should be consulted when a pacemaker or cardioverter-defibrillator malfunction is suspected.

2. Placing a magnet over the pacemaker disables the sensing mechanism, causing the pacemaker to fire at its preprogrammed rate regardless of the underlying intrinsic rhythm.
3. Magnetic resonance imaging may be safe in a pacemaker patient if the unit is programmed to an asynchronous mode and the patient is watched carefully.
4. Failure to sense occurs when the pacemaker generates output regardless of the patient's underlying rhythm; this is rarely an urgent problem.
5. Failure to pace is noted when a pacemaker spike is not seen when expected (after the lower rate-limiting interval has been exceeded); this can be devastating for a pacemaker-dependent patient, and temporary pacing may be required.
6. Failure to capture occurs when a pacemaker fires as expected but fails to depolarize the myocardium. This complication may require temporary pacing.

MYOCARDITIS IN THE INTENSIVE CARE UNIT

Myocarditis is defined as inflammation of the heart muscle.¹ Many different etiologic agents have been implicated in this disease, but viral infections are the most common cause. Myocarditis is also associated with autoimmune and other systemic diseases.² The clinical picture of myocarditis varies widely, from asymptomatic patients who recover without specific therapy and suffer no long-term sequelae to critically ill patients with heart failure and cardiogenic shock. There are no standardized, specific, and widely accepted criteria for making the diagnosis of myocarditis or for determining its cause in many patients.³ Last, there has been controversy regarding the most appropriate medical therapy for this condition.

On pathologic examination of myocardial biopsy specimens or at autopsy, myocarditis is usually apparent as infiltration of the myocardium with lymphocytes, macrophages, and fibroblasts, accompanied by myocyte necrosis (myocytolysis).³ It is this type of myocarditis, often termed *lymphocytic myocarditis*, that will be referred to in this chapter, unless otherwise specified. Other types of inflammatory reactions are seen less frequently in myocarditis, which involve giant cells, eosinophils, or granulomas and can be associated with specific clinical conditions.

In most patients with myocarditis, a specific cause is not found.⁴ In North America and Europe, the most common etiologic agent is presumed to be viral.¹ Coxsackie B enterovirus was considered the most common cause up to the 1990s, but human herpesvirus 6, cytomegalovirus, and parvovirus B19 have been implicated as causative agents more frequently over the past 20 years.² Hepatitis C is also a common etiology in some populations.⁵ Other viral causes include influenza, Epstein-Barr, and herpes simplex 1 and 2. Myocarditis is a common finding in patients infected with human immunodeficiency virus (HIV). However, the causative agent in these cases may be HIV or a secondary viral infection such as cytomegalovirus.^{1,6,7} Infectious illnesses such as Lyme disease, acute rheumatic fever, and diphtheria often have myocarditis as a prominent feature. In Central and South America, the most common cause of myocarditis is the protozoan *Trypanosoma cruzi*, the cause of Chagas' disease (Table 82-1). Systemic and autoimmune diseases such as systemic lupus erythematosus, polymyositis, scleroderma, sprue, Whipple's disease, and sarcoidosis can be complicated by myocarditis, and myocarditis can be a feature of the infiltrative cardiomyopathies seen in hemochromatosis or amyloidosis. Other specific forms of myocarditis include hypersensitivity or eosinophilic myocarditis, which can be caused by allergic reactions to medications including smallpox vaccination⁸ and giant cell myocarditis.⁹ Last, myocarditis can be associated with doxorubicin cardiomyopathy or with peripartum cardiomyopathy.^{10,11} (Box 82-1).

Unfortunately, clinical diagnosis of a specific viral cause of myocarditis is difficult. Antiviral antibody titers in acute and convalescent phase sera do not aid in the diagnosis, as viruses are highly prevalent in the general population and antibody levels vary over time and do not correlate well with the onset of symptoms of acute myocarditis.^{12,13} Viral cultures of tissue specimens are unreliable.⁴ The identification of viral genomes incorporated in myocyte DNA by the use of methods such as polymerase chain reaction (PCR) is highly suggestive but does not specifically prove that the virus is the cause.

PATHOGENESIS

Based on observations of human myocarditis and murine models of the disease caused by coxsackie B3, the pathogenesis of viral myocarditis can be described in three stages.^{2,14} The first stage is initiated by viral infection and replication within myocytes. Viral proteases and activation of proinflammatory cytokines initiate myocyte damage.¹⁵ The presence of this viral replication phase is difficult to detect clinically because patients may be asymptomatic during this phase or may only have nonspecific viremic symptoms. In addition, there is no rapid screening test to confirm viral infection. Parvovirus B19 may preferentially infect endothelial cells in coronary arteries, venules, and capillaries, and myocardial damage may be a result of coronary arteritis causing impairment of blood flow.¹⁶

The second stage involves host immune activation. Stimulation of cellular immunity as well as humoral responses attenuates viral proliferation and can result in recovery from the illness. However, unabated immune activation can result in activated T cells targeting myocardial antigens that cross-react with viral peptides. This reaction leads to the release of cytokines such as tumor necrosis factor, interleukin-1, and interleukin-6, resulting in further damage to myocytes and the cytoskeleton.^{1,15} Activation of CD4 cells and antibody production plays a less important pathogenetic role. This secondary immune response to viral infection may play a greater role in disease pathogenesis than the primary infection and may be genetically influenced.¹⁵ Incomplete clearing of virus or recurrent viral replication may also cause persistence of inflammation and myocardial damage. Evidence supporting these mechanisms includes the following: (1) myocardial biopsy with recombinant DNA techniques can detect viral genomes in 20% to 35% of patients; (2) tissue-specific autoantibodies have been detected in 25% to 73% of patients with evidence of myocarditis on biopsy, with antibodies directed against contractile, structural, and mitochondrial myocyte proteins; (3) inappropriate expression of the major histocompatibility complex can frequently be demonstrated on biopsy specimens¹; and (4) elevated levels of inflammatory cytokines are detected in patients with active myocarditis.

Either persistent overactivation of cellular immune activity or incomplete clearing with persistent or recurrent viral replication can lead to the third stage, which is marked by cellular apoptosis, ongoing necrosis, and fibrosis. Significant myocardial damage leads to left ventricular dilatation and remodeling, neurohormonal activation, systolic dysfunction, and manifestations of heart failure.^{15,17} These processes can then abate, with reduction in left ventricular size and improvement of left ventricular function, or can continue to progress with development of dilated cardiomyopathy, worsening ventricular function, and chronic heart failure. Chronic dilated cardiomyopathy is the major long-term sequela of acute myocarditis (Fig. 82-1).

CLINICAL PRESENTATION AND DIAGNOSIS

The incidence of myocarditis is difficult to determine, as many cases are mild with subclinical disease. Myocarditis is diagnosed on clinical grounds, as there are no specific clinical diagnostic criteria. The presentation of myocarditis varies widely. Patients can be asymptomatic,

TABLE 82-1 Causes of Myocarditis/Inflammatory Cardiomyopathy**INFECTIOUS MYOCARDITIS**

| | |
|-------------|---|
| Bacterial | <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Pneumococcus</i> , <i>Meningococcus</i> , <i>Gonococcus</i> , <i>Salmonella</i> , <i>Corynebacterium diphtheriae</i> , <i>Haemophilus influenzae</i> , <i>Mycobacterium</i> (tuberculosis), <i>Mycoplasma pneumoniae</i> , <i>Brucella</i> |
| Spirochetal | <i>Borrelia</i> (Lyme disease), <i>Leptospira</i> (Weil disease) |
| Fungal | <i>Aspergillus</i> , <i>Actinomyces</i> , <i>Blastomyces</i> , <i>Candida</i> , <i>Coccidioides</i> , <i>Cryptococcus</i> , <i>Histoplasma</i> , <i>Mucormycoses</i> , <i>Nocardia</i> , <i>Sporothrix</i> |
| Protozoal | <i>Trypanosoma cruzi</i> , <i>Toxoplasma gondii</i> , <i>Entamoeba</i> , <i>Leishmania</i> |
| Parasitic | <i>Trichinella spiralis</i> , <i>Echinococcus granulosus</i> , <i>Taenia solium</i> |
| Rickettsial | <i>Coxiella burnetii</i> (Q fever), <i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever), <i>R. tsutsugamushi</i> |
| Viral | RNA viruses: coxsackieviruses A and B, echoviruses, polioviruses, influenza A and B viruses, respiratory syncytial virus, mumps virus, measles virus, rubella virus, hepatitis C virus, dengue virus, yellow fever virus, Chikungunya virus, Junin virus, Lassa fever virus, rabies virus, human immunodeficiency virus-1 DNA viruses: adenoviruses, parvovirus B19, cytomegalovirus, human herpesvirus-6, Epstein-Barr virus, varicella-zoster virus, herpes simplex virus, variola virus, vaccinia virus |

IMMUNE-MEDIATED MYOCARDITIS

| | |
|--------------|---|
| Allergens | Tetanus toxoid, vaccines, serum sickness Drugs: penicillin, cefaclor, colchicine, furosemide, isoniazid, lidocaine, tetracycline, sulfonamides, phenytoin, phenylbutazone, methyl dopa, thiazide diuretics, amitriptyline |
| Alloantigens | Heart transplant rejection |
| Autoantigens | Infection-negative lymphocytic, infection-negative giant cell Associated with autoimmune or immune-oriented disorders: systemic lupus erythematosus, rheumatoid arthritis, Churg-Strauss syndrome, Kawasaki's disease, inflammatory bowel disease, scleroderma, polymyositis, myasthenia gravis, insulin-dependent diabetes mellitus, thyrotoxicosis, sarcoidosis, Wegener's granulomatosis, rheumatic heart disease (rheumatic fever) |

TOXIC MYOCARDITIS

| | |
|-----------------|--|
| Drugs | Amphetamines, anthracyclines, cocaine, cyclophosphamide, ethanol, fluorouracil, lithium, catecholamines, hemetine, interleukin-2, trastuzumab, clozapine |
| Heavy metals | Copper, iron, lead (rare, more commonly cause intramyocyte accumulation) |
| Miscellaneous | Scorpion sting, snake, and spider bites, bee and wasp stings, carbon monoxide, inhalants, phosphorus, arsenic, sodium azide |
| Hormones | Pheochromocytoma, vitamins: beriberi |
| Physical agents | Radiation, electric shock |

as myocarditis is found in 1% to 10% of autopsy specimens of young adults who had no history of cardiac illness. Myocarditis can be found at autopsy in up to 20% of cases of young, apparently healthy, adults who die suddenly and unexpectedly.^{1,4,11}

Patients ill with myocarditis present with nonspecific symptoms of dyspnea (72%), chest pain (32%), and symptoms of arrhythmia (18%).¹⁸ The presentation may be indistinguishable from acute coronary syndromes due to coronary artery disease. A viral prodrome with fever, malaise, and arthralgias may have preceded the presentation. Physical examination can show fever, tachycardia, S3 and S4 gallop sounds, and a pericardial rub if pericarditis is present. Signs of heart failure can be present, including pulmonary rales and wheezes, elevated jugular venous pressure, and peripheral edema. Murmurs of mitral regurgitation and tricuspid regurgitation may be heard. Infrequently, the presentation is fulminant and severe, with acute heart failure, pulmonary edema, and cardiogenic shock.⁴

The differential diagnosis includes acute myocardial infarction, isolated pericarditis, or chest pain from pulmonary causes, including pulmonary embolism or pneumonia. Generalized sepsis is also a consideration.

Laboratory findings can include leukocytosis, eosinophilia, and an elevated erythrocyte sedimentation rate. The cardiac biomarkers CPK, troponin T, and troponin I may be elevated, with troponin I sensitivity

reported as 34% to 53% and specificity reported as 89%.^{13,19} Rheumatologic serologic markers and HIV status should be evaluated.

The 12-lead electrocardiogram is an insensitive test for the diagnosis of myocarditis, most often showing sinus tachycardia, nonspecific ST segment depression, and T wave inversion. Patients may present with chest pain and ST segment elevation with a picture mimicking acute myocardial infarction or acute pericarditis. More severe cases can be associated with supraventricular or ventricular arrhythmias, conduction disturbances, and heart block.¹ QTc prolongation over 440 msec, QRS duration over 120 msec, and an abnormal QRS axis have been associated with a poorer prognosis.²⁰

Echocardiography is essential for diagnosing and quantitating regional or global left ventricular wall motion abnormalities, left ventricular and right ventricular size and function, and the presence of pericardial effusion and valvular regurgitation. Right ventricular involvement may be seen in 25% of patients.¹³ Fulminant myocarditis is characterized by a nondilated left ventricle with severe systolic dysfunction and increased wall thickness reflecting myocardial edema.²¹ Pericardial effusion may be present. Findings on myocardial nuclear scintigraphy are frequently abnormal, but this test is not useful in the diagnosis of myocarditis. Cardiac catheterization and coronary angiography are often necessary to exclude acute ischemia due to coronary artery disease as the cause of chest pain or acute heart failure.

Cardiac magnetic resonance imaging (CMR) with contrast enhancement is increasingly used in the diagnosis of myocarditis.^{22,23,24,25} This technique offers a noninvasive means to make this diagnosis. Diagnostic criteria include (1) focal or diffuse myocardial edema in T2-weighted images; (2) early gadolinium enhancement (EGE) on T1 imaging indicating inflammation and cell damage; and (3) late gadolinium enhancement (LGE) in subepicardial or mid-myocardial areas indicating necrosis and fibrosis. Myocardial edema may be subepicardial, transmural, or global and is not always associated with LGE. Abnormalities may be diffuse or patchy, often confined to the lateral free wall of LV or the base of the interventricular septum (Fig. 82-2). Diagnostic sensitivity is improved when all three techniques are assessed. The diagnostic accuracy of CMR is reported as 78% when 2 or 3 criteria are

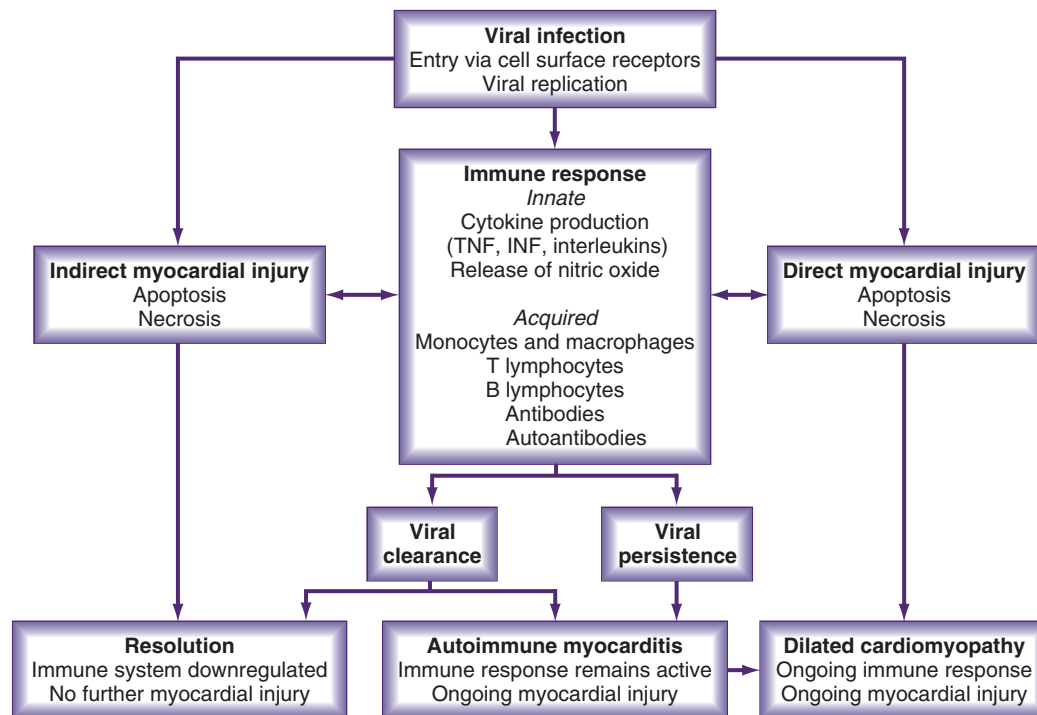

FIGURE 82-1 ■ The pathogenesis of viral myocarditis involves direct myocardial injury from viral infection as well as immune-mediated myocyte damage from cytokines, proteases, and autoantibodies. The outcome of these processes can be healing of inflammation and resolution of ongoing active myocarditis or chronic dilated cardiomyopathy. (Adapted from Blauwer LA, Cooper LT. Myocarditis. *Prog Cardiovasc Dis* 2010;52:274–88.)

FIGURE 82-2 ■ Cardiac magnetic resonance imaging with late gadolinium enhancement: normal and abnormal findings in myocarditis. **(A)** Normal myocardium with no evidence of irreversible myocyte injury. **(B)** Regional subepicardial enhancement of the lateral wall (arrow). **(C)** Subepicardial enhancement of lateral and midwall enhancement of the septal wall (arrows). **(D)** Diffuse subepicardial enhancement. (From Friedrich MG, Sechtem U, Schulz-Menger J, Holmvang G, Alakija P, Cooper LT, et al. Cardiovascular magnetic resonance in myocarditis: a JACC White Paper. *J Am Coll Cardiol* 2009;53(17):1475–87.)

present and 68% when only late gadolinium enhancement is present. CMR is more likely to be abnormal when performed more than 7 days after the onset of symptoms. CMR may also detect pericardial effusion (seen in 32%–57% of patients) and gives information regarding LV function. CMR can also be used to direct myocardial biopsy in patients with patchy uptake. The value of CMR for assessing prognosis is unknown.^{26–28}

Advantages of CMR include that it is noninvasive and low risk, has no sampling error (a problem with endomyocardial biopsy, see later discussion), and can be used serially over time to assess a patient's

course. However, CMR results may be normal in patients with milder forms of myocarditis, and it does not distinguish between viral and other etiologies of the disease. CMR is difficult to use in critically ill patients.

Endomyocardial Biopsy

Percutaneous endomyocardial biopsy (EMB) is used to aid in the diagnosis of myocarditis and is considered the definitive diagnostic technique. The Dallas criteria have been accepted as the standard for

histopathologic diagnosis, but the utility of the Dallas criteria is strongly debated (see later discussion). These criteria define *active myocarditis* as the presence of an inflammatory myocardial infiltrate (more than 5 lymphocytes per high-power field) accompanied by myocyte necrosis. *Borderline myocarditis* is defined as inflammation without myocyte necrosis. However, there is no difference in prognosis in patients with either of these biopsy results.¹⁰ Thus, lymphocyte infiltration (with or without myocyte necrosis) is the most important diagnostic criterion. A more recent pathologic definition from the World Heart Federation defined *myocarditis* as the presence on EMB of a focal or diffuse mononuclear cell infiltrate of lymphocytes and macrophages, with more than 14 cells/mm², and emphasized that immunohistochemistry to identify upregulated HLA proteins and polymerase chain reaction (PCR) to investigate viral genomes should also be performed.^{20,29,30} Viral myocarditis is considered present when there is evidence of active inflammation with a positive molecular test for virus on EMB. Autoreactive or autoimmune myocarditis is diagnosed when inflammation is present without viral markers.³¹

A positive EMB has a high positive predictive value, but there are a number of significant limitations.¹⁰ A high frequency of interobserver variation has been noted among pathologists in applying the Dallas criteria. Biopsies are not sensitive in diagnosing myocarditis, as various series have reported positive right ventricular biopsy results in only 10% to 67% of patients with myocarditis suspected on clinical grounds or with recent-onset idiopathic dilated cardiomyopathy. This variability may relate to the timing of biopsies with respect to the stage or chronicity of the patient's illness. In addition, the myocardial inflammation may not be diffuse and may be patchy or may predominantly involve the left ventricle, so random right ventricular biopsies may miss the affected myocardium.²⁹ Thus, diagnostic yields are improved by performing a biopsy earlier in a patient's clinical course, taking 3 to 6 biopsy specimens, and performing left ventricular biopsies. In addition, immunohistochemical staining for human leukocyte antigens can improve diagnostic sensitivity.^{14,32} EMB should be performed in centers with a high-volume experience, with proven safety and availability of appropriate pathologic techniques.³³ Recent reports indicate a very low rate of serious complications related to EMB in experienced centers, <0.1%.³¹ It is important to emphasize that a negative biopsy finding does not preclude the diagnosis of myocarditis.

Endomyocardial biopsy should be strongly considered in cases of suspected myocarditis when pathology results will affect management decisions. A recent AHA/ACC/ESC scientific statement offered recommendations concerning the appropriate use of EMB based on patients' clinical presentations.³⁴ EMB was deemed useful, beneficial, and effective (class I indication) in patients with acute heart failure with hemodynamic compromise, after exclusion of causes such as coronary artery disease. EMB in this setting is necessary to differentiate giant cell myocarditis and eosinophilic myocarditis, which most often present with severe heart failure or arrhythmias, from lymphocytic myocarditis, as immunosuppressive therapy is mandated in the first two conditions. A class I indication for EMB was also recommended for patients with new onset, subacute heart failure, or illness duration of 2 weeks to 3 months and in those who fail to improve with medical therapy for heart failure or demonstrate severe ventricular arrhythmia or advanced heart block. EMB should be considered if causes such as sarcoidosis or collagen vascular disease are suspected and should be performed to diagnose giant cell myocarditis or eosinophilic myocarditis.³⁵ Endomyocardial biopsy should always be performed before initiating immunosuppressive therapy (Box 82-2).

An algorithm has been proposed outlining the steps for evaluating patients suspected of having acute myocarditis (Fig. 82-3).

CLINICAL COURSE AND PROGNOSIS

The clinical course and prognosis of acute myocarditis are variable. The majority of patients diagnosed with myocarditis will improve, and those with mild symptoms most often recover without complications. Eight to 12% of young, apparently healthy adults who die suddenly

BOX 82-2 Indications for Endomyocardial Biopsy

Exclusion of potential common etiologies of dilated cardiomyopathy (familial, ischemic, alcohol, postpartum, cardiotoxic exposures) and the following:

- Subacute or acute symptoms of heart failure refractory to standard management
- Substantial worsening of ejection fraction despite optimized pharmacologic therapy
- Development of hemodynamically significant arrhythmias, particularly progressive heart block and ventricular tachycardia
- Heart failure with concurrent rash, fever, or peripheral eosinophilia
- History of collagen vascular disease such as systemic lupus erythematosus, scleroderma, or polyarteritis nodosa
- New-onset cardiomyopathy in the presence of known amyloidosis, sarcoidosis, or hemochromatosis
- Suspicion for giant cell myocarditis (young age, new subacute heart failure, or progressive arrhythmia without apparent etiology)

Adapted with permission from Wu L, Lapeyre A, Cooper L. Current role of endomyocardial biopsy in the management of dilated cardiomyopathy and myocarditis. *Mayo Clin Proc* 2001;76:1030–8.

from a cardiac cause are found to have myocarditis at autopsy, suggesting that patients even with apparently mild illness can suffer fatal arrhythmias.¹⁴ In over 50% of patients, clinically recognized myocarditis will resolve in 4 weeks. However, 25% will develop persistent abnormalities of ventricular function, and roughly 10% to 20% may develop dilated cardiomyopathy with chronic, severe heart failure.^{3,30} Fifteen to 25% of patients who present with new-onset dilated cardiomyopathy have evidence of antecedent myocarditis.³ Patients with heart failure and left ventricular dysfunction will experience spontaneous resolution of their illness within 12 months in up to 40% of cases, without long-term sequelae. Roughly one-quarter of patients with acute myocarditis and ejection fraction below 35% will improve, one-half will develop chronic cardiomyopathy and heart failure, and one-quarter will deteriorate and may be candidates for cardiac transplantation.³⁶

Examining the patient population under study and the criteria used for diagnosing myocarditis is important in any series assessing prognosis and mortality. No clinical markers reliably predict which patients with myocarditis will recover or worsen.¹⁰ In the Myocarditis Treatment Trial, the 1-year mortality rate was 20% and the 5-year mortality rate was 56% in patients with biopsy-confirmed lymphocytic myocarditis.³⁷ A series of 21 patients with active myocarditis on biopsy was analyzed for predictors of disease course. Variables assessed included baseline hemodynamics, use of ventilatory and circulatory support, and serum cardiac biomarkers. Overall, there was a 37% mortality rate (8 of 21), with death occurring at 27.6 ± 6.9 days. Factors predicting a worse prognosis included hypotension (mean 84/49 mm Hg), higher pulmonary capillary wedge pressure (mean, 24 mm Hg), and use of mechanical ventilation. Factors that were not predictive of mortality included sex, age, heart rate, cardiac index, peak CPK, and the use of intraaortic balloon counterpulsation for circulatory support.³⁸ Another trial reported 181 patients with myocarditis confirmed by EMB using the Dallas criteria, immunohistochemical staining, and PCR. LV biopsy was performed in 90% of patients. Patients were followed for an average of 59 months, and 22% died or received cardiac transplantation. Multivariate analysis concluded that functional class III and IV heart failure and a positive immunohistochemical result were the only predictors of a poor outcome, and treatment with beta-blockers was associated with better outcomes³² (Fig. 82-4). Other series have reported that LV ejection fraction less than 40% and right ventricular dysfunction also predict a poorer prognosis.¹⁴

Fulminant Myocarditis

A small percentage of patients with acute myocarditis present critically ill with acute severe heart failure and cardiogenic shock. This presentation is termed *fulminant myocarditis*. Most often these patients give

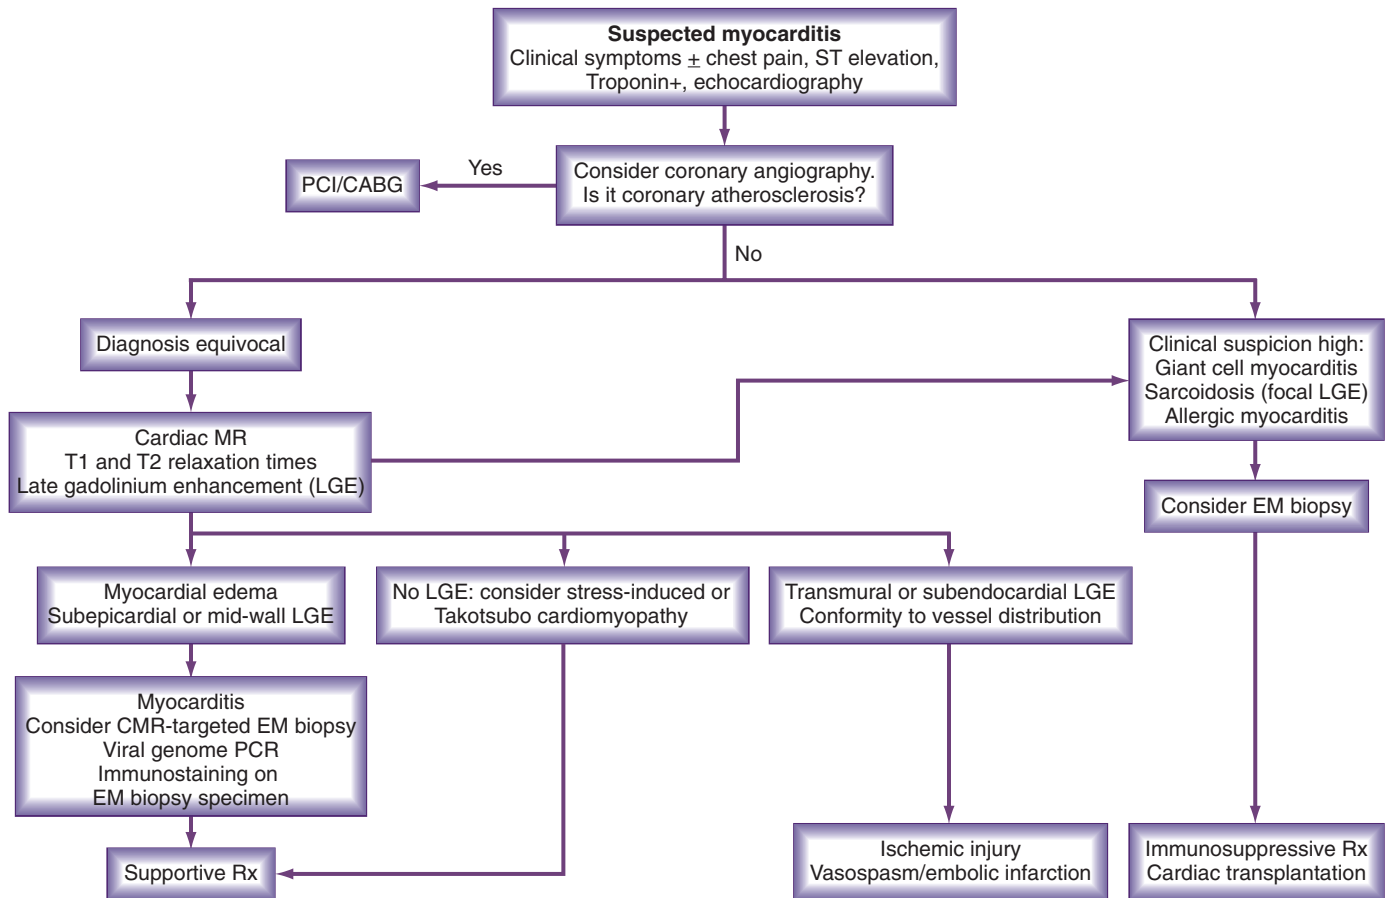

FIGURE 82-3 ■ Diagnostic algorithm for suspected acute myocarditis. (Adapted from Nelson KH, Li T, Afonso L. Diagnostic approach and role of MRI in the assessment of acute myocarditis. *Cardiol Rev* 2009;17:24–30.)

FIGURE 82-4 ■ Prognosis for patients with acute myocarditis was predicted by three factors: NYHA functional class, positive immunohistology for myocarditis at EMB, and therapy with beta-blockers. (Adapted from Kindermann I, Kindermann M, Kandolf R, et al. Predictors of outcome in patients with suspected myocarditis. *Circulation* 2008;118:639–48.)

a history of recent fever and symptoms of a viral illness during the previous several weeks, with a distinct time of onset of heart failure symptoms. This presentation can be contrasted with that of patients with myocarditis who have acute heart failure, but not cardiogenic shock, who demonstrate a less distinct time of onset of heart failure symptoms and less severe hypotension. Direct cytolysis of myocytes caused by viral infection and replication is felt to be particularly important in fulminant myocarditis. Early and extensive loss of myocytes and myocardial tissue leads to the rapid development of severe heart failure.

In a study of 147 patients presenting with heart failure due to biopsy-positive active myocarditis with ejection fraction less than 40%, 10% of patients were diagnosed with fulminant myocarditis, and 90% had acute nonfulminant myocarditis.¹⁰ The patients with fulminant myocarditis needed hemodynamic support with high-dose vasopressors or left ventricular assist devices. The acute myocarditis patients had more stable hemodynamics and did not require vasopressors or received them at low doses. Patients with fulminant myocarditis tended to be younger and had higher heart rates and lower systemic blood pressure. There was no difference between the groups in mean pulmonary capillary wedge pressure or cardiac index. With aggressive treatment, patients with fulminant myocarditis actually had better survival rates: 93% at 1 year and 93% at 11 years. Patients with acute myocarditis had an 85% 1-year survival rate and a 45% survival rate at 11 years. Patients with lower pulmonary capillary wedge pressure or higher cardiac index at presentation also had better survival. In another study of myocarditis in children, 38% of myocarditis cases were fulminant.³⁹

In summary, fulminant myocarditis has a distinct clinical course, with critical illness at presentation but with excellent long-term survival after recovery from the acute phase of illness. EMB is essential for management as immunosuppressive therapy is recommended if active inflammation is documented.¹³ Healing of myocardial injury and significant improvement of left ventricular systolic function can be expected. Therefore, an aggressive approach to therapy, including the use of ventricular assist devices or other mechanical assist devices, without resorting to early cardiac transplantation, is warranted.¹⁰

Giant Cell Myocarditis

Giant cell myocarditis is a distinct form of myocarditis, characterized by severe heart failure, life-threatening ventricular arrhythmias, and/or high-grade heart block. It has a rapidly progressive course, without significant likelihood of spontaneous resolution. On endomyocardial biopsy, infiltration with inflammatory giant cells and lymphocytes is seen. Although the pathogenesis is not clear, it is believed to be an autoimmune disorder, possibly triggered by a viral infection; it often occurs in patients with other autoimmune disorders.⁴⁰ CD4 T-lymphocytes are thought to play an important role. A total of 63 patients with biopsy-confirmed giant cell myocarditis were studied retrospectively.⁴¹ Heart failure was the presentation in 75% of cases; 14% presented with ventricular arrhythmias, and 11% presented with chest pain, an abnormal electrocardiogram, or heart block. There was an association with inflammatory bowel disease in 8% of cases. Survival was poor, with a median time of 5.5 months to death or cardiac transplantation. EMB is essential to make this diagnosis. In this uncontrolled series, immunosuppressive therapy was associated with prolonged survival: from 3 months in 30 patients not given immunosuppressive drugs and 3.8 months in patients treated with prednisone, to 11.5 months in patients given prednisone plus azathioprine and 12.6 months in patients who were given cyclosporine as part of their regimen. Other options for immunosuppressive therapy include anti-tissue necrosis factor therapy and monoclonal antibodies to CD3 cells.^{12,31} The prognosis after cardiac transplantation was also worse compared with other forms of heart disease, with a 30-day mortality rate of 15% and a 26% mortality rate during the 3.7-year posttransplant follow-up period. Twenty-six percent of patients had giant cell infiltrates seen in their transplanted heart at an average time of 3 years after transplant.

Eosinophilic Myocarditis

Eosinophilic myocarditis, also termed *hypersensitivity myocarditis*, is a rare form of myocarditis characterized by eosinophilic infiltration and degranulation on endomyocardial biopsy. The pathogenesis is thought to involve a direct role of eosinophil-mediated myocyte damage. There can be associated arteritis. This entity is distinct from eosinophilic endocarditis (Löffler's endocarditis). The clinical manifestations are not specific, aside from a high incidence of eosinophilia in peripheral blood. Patients usually present with heart failure due to left ventricular systolic dysfunction. Fever and rash may be present. Untreated, the disease is often rapidly fatal.⁸

The cause is believed to be a hypersensitivity reaction, usually to medication or rarely in association with parasitic infections. Drugs most often implicated are sulfonamides, diuretics, angiotensin-converting enzyme (ACE) inhibitors, cephalosporins, digoxin, and dobutamine. Eosinophilic myocarditis has been reported to occur weeks after smallpox vaccination, with an incidence of 1 in 16,000 vaccinated.⁴² The clinical course is unfavorable, often with rapidly worsening heart failure and sudden death due to ventricular arrhythmia. Treatment involves the discontinuation of all potentially offending medications and the use of high-dose corticosteroids with azathioprine.³¹ Excellent responses to corticosteroids, as well as some spontaneously resolving illness, have been reported.^{43,44}

Eosinophilic myocardial infiltration has been reported in 2% to 7% of myocardial biopsy specimens of patients awaiting cardiac transplantation or in the explanted heart after transplant. The cause is unclear,

but evidence implicates dobutamine therapy, sodium bisulfite used as a preservative in dobutamine solutions, and the use of left ventricular assist devices. The presence of eosinophilic myocarditis in this setting did not have an adverse effect on posttransplant survival and did not recur in the transplanted heart.^{45,46}

THERAPY

General Management of Heart Failure

The treatment of myocarditis is based on the clinical presentation. Patients with mild disease can be treated expectantly, with dietary sodium restriction and avoidance of strenuous exercise for several weeks or months.³ Animal models indicate that strenuous exercise can worsen myocarditis. Elimination of unnecessary medications is important in patients with eosinophilia.

Nonsteroidal antiinflammatory drugs should be avoided because they may worsen myocarditis.⁴ The routine use of anticoagulants for prophylaxis of systemic emboli is not recommended. Patients who present with symptoms of arrhythmia or heart failure should be hospitalized, with continuous cardiac rhythm monitoring performed for evaluation of potential life-threatening arrhythmias or conduction abnormalities. If these are diagnosed, they are treated in a similar manner as in patients with other causes of heart disease, using antiarrhythmic drugs or pacemakers. However, a period of observation is recommended to assess for improvement of cardiac function before implantation of an ICD.

Data from studies of murine models of myocarditis support the use of angiotensin-converting enzyme inhibitors, angiotensin blockers, and beta-blockers. These drugs reduce inflammation and lessen necrosis and fibrosis.^{2,3,14,26} There are convincing data in humans supporting the use of these medication as well as aldosterone antagonists in patients with dilated cardiomyopathy. Therefore, in patients with myocarditis and heart failure, the use of standard multidrug medical therapy for heart failure and left ventricular systolic dysfunction is indicated.^{3,11} These medications have been shown to improve symptoms, prolong life, and regress the adverse left ventricular remodeling in patients with dilated cardiomyopathy of various causes.^{47,48,49}

Treatment with ACE inhibitors should be initiated at low doses, with upward titration to maximally tolerated doses. Patients should be closely monitored for potential side effects, including renal insufficiency, hyperkalemia, and angioedema. Relative contraindications to the use of ACE inhibitors include renal failure, hyperkalemia, bilateral renal artery stenosis, and hepatic failure. Patients with hypotension should be treated with parenteral vasopressors or circulatory assist devices before initiation of low-dose ACE inhibitor therapy.

As described above, beta-adrenergic blockade was associated with improved survival in a multivariate analysis of patients with acute myocarditis.³² Large randomized, controlled clinical trials, which included patients with idiopathic dilated cardiomyopathy, have unequivocally shown benefit from beta-blockers in patients with left ventricular systolic dysfunction,⁵⁰⁻⁵⁴ and these agents should also be used in patients with heart failure due to myocarditis. Beta-blockers should be initiated after patients are on a stable dose of ACE inhibitors and when signs of fluid overload have resolved. Contraindications to beta-blocker therapy include bronchospastic disease or severe chronic obstructive lung disease, heart block, or significant underlying bradycardia. Hypotension should be corrected before initiating beta-blocker therapy.

Digoxin has been shown in animal models to decrease levels of cytokines, but digoxin was associated with adverse outcomes in one murine model of myocarditis. Digoxin can be useful in helping to control ventricular rates in patients with atrial fibrillation. The use of digoxin should be considered in patients with significant left ventricular systolic dysfunction, after ACE inhibitors and beta-blockers have been initiated. However, no survival benefit for digoxin has ever been shown in patients with heart failure due to dilated cardiomyopathy.⁵⁵ Contraindications to the use of digoxin include renal failure or heart block.

Last, the use of the aldosterone antagonist spironolactone has been shown to have symptomatic and survival benefits in patients with class III-IV chronic systolic heart failure.⁵⁶ In experimental models, these agents can reverse the progressive myocardial fibrosis that occurs in the remodeling process of dilated cardiomyopathy. These agents have not been studied in patients with myocarditis, but their use should be strongly considered in patients with severe left ventricular dysfunction (ejection fraction less than 35%) and symptomatic heart failure.² Contraindications to the use of aldosterone antagonists include renal insufficiency, with serum creatinine levels above 2.0 mg/dL or hyperkalemia. Serum potassium levels need to be carefully monitored during initiation and dose titration.

In critically ill patients with severe heart failure and a low cardiac index, without serious hypotension, parenteral vasodilators should be used. Intravenous nitroprusside reduces systemic vascular resistance, mean systemic arterial pressure, and pulmonary capillary wedge pressure and can improve cardiac index. It is used with invasive hemodynamic monitoring with a pulmonary artery catheter, to best gauge the appropriate dose of medication and to accurately assess response to therapy. Prolonged use of nitroprusside is associated with accumulation of the toxic metabolites. Intravenous nitroglycerin is also an effective venodilator and coronary vasodilator, with less arterial dilating property than nitroprusside. The use of nitroglycerin in cases of myocarditis has not been studied. Patients often develop tolerance to this drug.^{57,58}

Patients with severe myocarditis may develop cardiogenic shock, respiratory failure, and end-organ hypoperfusion. In these instances, treatment with inotropic agents or vasopressors is indicated. Dobutamine is a potent β_1 -agonist with fewer β_2 - and α -agonist properties. Dobutamine has favorable short-term hemodynamic effects, increasing myocardial contractility, reducing systemic vascular resistance, and reducing pulmonary capillary wedge pressure. However, dobutamine can be proarrhythmic, and patients can develop tolerance to the drug. Milrinone is another parenteral inotropic agent, which works by inhibiting phosphodiesterase. This drug leads to increased inotropy and decreased systemic vascular resistance and pulmonary capillary wedge pressure, with resultant increased stroke volume and cardiac index. Milrinone may cause hypotension. It is less proarrhythmic than dobutamine and does not induce tolerance.^{59,60} Arterial vasoconstrictors such as norepinephrine and dopamine can be used in patients with refractory hypotension and poor end-organ perfusion.

In patients with fulminant myocarditis or cardiogenic shock not responding to pharmacologic therapy, intraaortic balloon counterpulsation should be used. Mechanical ventricular assist devices (VAD) are used for patients requiring greater hemodynamic support. These devices provide physiologic cardiac output and left ventricular afterload reduction and may allow time for spontaneous improvement in left ventricular function to occur. Complications of VADs include local site infection, sepsis, thromboemboli, and device failure. Extracorporeal membrane oxygenation (ECMO) is another option for circulatory support.

In patients with severe myocarditis, mechanical circulatory support can be used to improve hemodynamics, end-organ perfusion, and coronary flow during the time necessary for spontaneous resolution of left ventricular dysfunction. Beneficial reverse remodeling may occur while patients are on mechanical support. Patients with fulminant myocarditis should be given a reasonable time to recover ventricular function before cardiac transplantation is performed.⁶¹

There are several unresolved issues regarding VAD use in patients with myocarditis. These include appropriate patient selection, timing of VAD placement, best medical therapy during VAD support, and optimal duration of VAD support. A 50-day course of VAD support in the earlier-cited study allowed identification of 50% of those patients who ultimately recovered, and a 90-day course identified 80% of patients who recovered. The optimal means of serial assessment of native heart function while on VAD support needs to be delineated, and the best weaning protocol also needs definition.

Cardiac transplantation is the final option for treating critically ill patients with myocarditis. However, these patients may have a higher

TABLE 82-2

Medical Therapy and Advanced Supportive Therapies for Heart Failure in Acute Myocarditis

rate of transplant rejection and a lower survival rate compared with patients transplanted for ischemic or other causes of cardiomyopathy (Table 82-2).¹¹

Immunosuppressive Therapy

Because autoimmune mechanisms are responsible for myocardial injury and the clinical manifestations of myocarditis, therapy with immunosuppressive drugs has been studied. However, given the high rate of spontaneous recovery of left ventricular function, placebo-controlled trials are essential to properly evaluate the effects of therapy. In addition, heterogeneous patient populations consisting of patients with acute myocarditis and chronic dilated cardiomyopathy have been included in immunosuppressive trials, confounding the interpretation of results.

High-dose daily prednisone therapy was used for a 3-month course in 102 patients with dilated cardiomyopathy, 59% of whom were classified as having “reactive” myocarditis on endomyocardial biopsy.⁶² The authors found a significant improvement in left ventricular ejection fraction at 3 months in treated patients with reactive myocarditis, but this improvement was not sustained at 9 months. Improvement did not occur in patients with nonreactive biopsies treated with prednisone. No significant mortality benefit from immunosuppressive treatment was noted, although this was not a prespecified primary endpoint.

The Myocarditis Treatment Trial enrolled 111 patients with a positive endomyocardial biopsy finding and left ventricular ejection fraction less than 45%, with a duration of illness of less than 2 years.³⁷ Three treatment groups were compared: daily prednisone plus azathioprine, prednisone plus cyclosporine, and placebo. Mortality was 20% at 1 year and 56% at 3 years. These investigators found no difference in ejection fraction at week 28 or week 52, no change in left ventricular size at week 28, and no difference in 1-year mortality between treated and untreated groups. Their conclusion was that these immunosuppressive strategies were not beneficial. Significant limitations of this study include a 30% dropout rate and significant interobserver variability among pathologists’ diagnoses of biopsy specimens despite using the Dallas criteria.

In view of the limitations of histopathologic diagnosis using the Dallas criteria, another group of investigators utilized immunohistologic markers of inflammation, upregulation of HLA, to diagnose active myocarditis as an indication for immunosuppressive therapy.⁶³ This criterion has the advantage of indicating that autoimmunity is playing a role in pathogenesis. Also, since HLA is distributed throughout the entire myocardium, biopsy sampling error is eliminated as a confounding variable in assessing response to therapy. In this study, 84 of 202 patients with chronic (>6 months) idiopathic dilated cardiomyopathy (ejection fraction <40%) were found to have strong expression of HLA in biopsy specimens and were randomized to receive placebo or prednisone plus azathioprine for 3 months. At 3 months’ follow-up,

a significant improvement in the prespecified secondary endpoints of left ventricular ejection fraction, left ventricular volumes, and functional capacity was seen in the treated group, and this improvement was maintained at 2 years (71.8% improvement in the treated group vs. 30.8% in the untreated group). However, there was no improvement in the prespecified composite primary endpoint of death, cardiac transplant, or hospital readmission. This study was limited by a 31% dropout rate.

In another study, patients with positive endomyocardial biopsy specimens and progressive heart failure who responded to 6 months of therapy with prednisone and azathioprine were more likely to have circulating cardiac autoantibodies and no viral genome in their myocardium as compared with nonresponders.⁶⁴ Another randomized, placebo-controlled trial of prednisone plus azathioprine was performed in 85 patients with chronic heart failure (>6-month illness) with active lymphocytic myocarditis on EMB and absence of virus genome on PCR. There was significant improvement in LV ejection fraction in the treated group (average ejection fraction increased from 26.5% to 45.6%) and no improvement in controls (average ejection fraction dropped from 27.7% to 21.3%). In addition, there was significant improvement in LV dimensions and patients' functional status in the group receiving immunosuppression. This study suggests that this therapy may have favorable effects in patients who persist with active myocardial inflammation after virus has been cleared⁶⁵ (Fig. 82-5).

Studies have suggested that in patients with heart failure and low ejection fraction, intravenous immunoglobulin (IVIg) has a pronounced antiinflammatory effect as measured by circulating levels of inflammatory markers.⁶⁶ Uncontrolled studies suggest benefit in patients with myocarditis from treatment with intravenous immunoglobulin.^{67,68} However, a placebo-controlled double-blind trial of intravenous immunoglobulin in patients with myocarditis or idiopathic dilated cardiomyopathy of less than 6 months' duration showed no significant improvement with therapy as assessed by ejection fraction or functional capacity at 6 and 12 months.⁶⁹ In this study, the average left ventricular ejection fraction improved from $25 \pm 8\%$ at baseline to $41 \pm 17\%$ at 6 months in both treated and untreated groups. One-year event-free survival rate was 91.9% in both groups, indicating a favorable prognosis. Therefore, the use of IVIg is not supported by any randomized trial.⁷⁰ Studies are ongoing evaluating the use of IVIg and antiviral therapies in patients with chronic myocarditis with persistent viral genome on EMB specimens.¹⁶ Evaluating the mechanisms of myocardial recovery during VAD support may also help direct research toward novel approaches to the treatment of myocarditis.

In summary, there is no evidence that patients with lymphocytic myocarditis or idiopathic dilated cardiomyopathy benefit from the routine use of immunosuppressive therapy. However, this treatment approach should be considered in patients with myocarditis and active inflammation seen on endomyocardial biopsy findings, those who develop early signs of severe heart failure, and those who are shown to experience progressive worsening of left ventricular function. Last, immunosuppressive therapy should be used in patients with myocarditis associated with autoimmune diseases such as SLE, eosinophilic or granulomatous forms of the disease, and in giant cell myocarditis (Box 82-3).

BOX 82-3

Indications for Immunosuppressive Therapy in Myocarditis

Inflammation present on endomyocardial biopsy and:

1. Continued severe heart failure symptoms despite good medical therapy for heart failure
2. Progressive worsening of heart failure symptoms or LV systolic function despite good medical therapy
3. Fulminant myocarditis
4. Presence of giant cell myocarditis
5. Presence of eosinophilic myocarditis
6. Presence of myocarditis in association with a systemic autoimmune disease, e.g., SLE, inflammatory bowel disease, polymyositis

FIGURE 82-5 ■ Left ventricular function and size at baseline (clear bars) and at 6 months (dark bars) in patients with myocarditis and active inflammation and absence of viral genome on endomyocardial biopsy. Group 1 was treated with immunosuppressive therapy and group 2 with placebo. (From Frustaci A, Russo MA, Chimenti C. Randomized study on the efficacy of immunosuppressive therapy in patients with virus-negative inflammatory cardiomyopathy: the TIMIC trial. *Eur Heart J* 2009;30:1999.)

Summary

The most common cause of myocarditis is viral infection, and autoimmune mechanisms are involved in pathogenesis. Patients with myocarditis can present with acute chest pain, mimicking acute ischemic heart disease or other cardiopulmonary illnesses, or can present with heart failure due to dilated cardiomyopathy. A smaller percentage of patients present with acute heart failure due to severe left ventricular systolic dysfunction. Oral and parenteral pharmacologic therapies that are used in patients with heart failure not caused by myocarditis are

also used in these patients. Fulminant myocarditis is characterized by severe heart failure and cardiogenic shock. These patients need intensive, aggressive pharmacologic therapy and may require mechanical circulatory support. Cardiac magnetic resonance imaging is an important tool in the diagnosis of myocarditis. Endomyocardial biopsy is a safe technique used in the diagnosis of myocarditis in sicker patients to decide on immunosuppressive therapy, although it is limited by sampling error and by current histopathologic techniques for assessing disease activity. Newer immunohistologic methods may better define those patients who will respond to immunosuppressive therapy. Patients with myocarditis and progressive myocardial failure, despite conventional heart failure therapy, should be considered for immunosuppressive therapy on a case-by-case basis. Such patients should be followed with serial measures of left ventricular performance and endomyocardial biopsies.

TRANSIENT APICAL BALLOONING SYNDROME

A distinctive cardiomyopathy with acute onset, frequently precipitated by emotional or physical stress, is termed *transient apical ballooning syndrome* (TABS) due to its distinctive left ventricular wall motion abnormality. This cardiomyopathy was first described in patients in Japan in 1991.⁷¹ This syndrome has subsequently been described in the United States and Europe.^{72,73} It is characterized by the sudden onset of chest pain and/or dyspnea, ECG changes mimicking acute myocardial infarction (AMI), and mild elevation of serum myocardial biomarkers. The syndrome is precipitated by extreme emotional or physical stress in >70% of cases.⁷⁴ The characteristic left ventricular wall motion abnormality is akinesis or dyskinesis of a large area of the left ventricular apex (Figs. 82-6 and 82-7). Coronary artery stenosis is not present. This syndrome has been called TABS, stress cardiomyopathy, or takotsubo cardiomyopathy, so named because the takotsubo pot used by Japanese fishermen to trap octopus has a shape similar to the left ventricle in this condition ("short neck, round flask").⁷³⁻⁷⁶

There is a marked preponderance of elderly females affected by this condition, 86% to 100% in reported series, with a mean age of 63 to 67 years. However, many subsequent reports have described this condition in younger patients. Chest pain is the presenting symptom in 66% to 90% of patients, and 15% to 20% will present with dyspnea, pulmonary edema, or shock. The most common ECG changes seen are ST-segment elevation or marked T-wave inversions in the precordial leads. These findings are indistinguishable from acute myocardial infarction. Elevation of CK-MB and troponin is seen in the majority of patients, but the enzyme rise is typically milder than would be expected given the marked ECG and left ventricular wall motion abnormalities. Precipitators of TABS include arguments with family members, the death of loved ones, or sudden financial setbacks. Physical stresses include medical procedures such as thoracentesis or biopsy, institution of cancer chemotherapy or hemodialysis, hip fracture, and noncardiac surgeries.

Echocardiography and left ventriculography show moderate to severe left ventricular dysfunction in these patients, with characteristic hyperkinesis of inferior-basal and basal-septal segments and severe hypokinesis or dyskinesis involving mid-anteroseptal, apical, and inferior-apical wall segments. A smaller percentage of patients will demonstrate a different contraction abnormality, with akinesis involving the mid-anterior and mid-inferior walls, with normal motion or hypercontractility of the apex and basal segments. Acutely, the left ventricular ejection fraction is reduced to 20% to 40%.^{74,75} Up to 20% of patients may demonstrate a left ventricular outflow tract gradient due to basal septal hyperkinesis and transient systolic anterior motion of the anterior leaflet of the mitral valve.^{72,73,77}

Patients with TABS often present critically ill, with pulmonary edema, hypotension, and shock. Cardiogenic shock develops from marked left ventricular systolic dysfunction and decreased stroke volume. Shock can also be exacerbated by the development of a left ventricular outflow tract gradient.⁷⁸ Cardiogenic shock has been reported in 5% of patients at presentation and has occurred during the course of the illness in 6% to 46% of patients in different series.^{72,74-76,79}

FIGURE 82-6 ■ End-diastolic and end-systolic apical four- and two-chamber echocardiographic views demonstrating the typical apical and mid-ventricular LV wall motion abnormalities of a patient with transient apical ballooning syndrome. (From Gianni M, Dentali F, Grandi AM, Sumner G, Hiralal R, Lonn E. Apical ballooning syndrome or takotsubo cardiomyopathy: a systematic review. *Eur Heart J* 2006;27:1523–9.)

FIGURE 82-7 ■ Left ventriculogram showing typical left-ventricular wall motion abnormalities in transient apical ballooning syndrome. Arrows in systole indicate hyperkineses of basal interior and anterior segments with severe hypokinesis of remaining wall segments. (From Sharkey SW, Lesser JR, Zenovich AG, Maron MS, Lindberg J, Longe TF, et al. Acute and reversible cardiomyopathy provoked by stress in women from the United States. *Circulation* 2005;111:472–9.)

Suspicion of TABS and urgent diagnosis are important, as therapy and prognosis differ substantially from AMI. TABS should not be treated with thrombolytic therapy, as coronary occlusion is not involved in the pathogenesis. If cardiogenic shock develops, treatment with intraaortic balloon counterpulsation (IABP) is indicated. Inotropic therapy should be used judiciously or not at all. Dobutamine and other beta agonists may worsen cardiogenic shock by increasing hyperkinesis of the basal portion of the heart and causing or aggravating a left ventricular outflow tract gradient. Several case reports describe patients with TABS with hypotension who developed frank cardiogenic shock after initiation of inotropic therapy. Since a hyperadrenergic state is proposed to be a major pathogenic mechanism, empirical use of beta-blockers while patients are being supported with IABP has been successful. Echocardiography can be useful to guide therapy. For those with extensive wall motion abnormalities but no outflow obstruction, IABP support without beta-blockers is recommended. Administration of the alpha agonist phenylephrine can also be considered in cases with a high left ventricular outflow tract gradient, as this drug increases afterload, causing left ventricular dilatation and a decrease in mitral valve systolic anterior motion and lowering of intraventricular gradients.⁷⁷ TABS is associated with a good prognosis; therefore, aggressive therapy of hemodynamic compromise and cardiogenic shock is indicated. In almost all patients, the marked apical wall motion abnormalities begin to improve within days, and left ventricular function can be expected to recover to normal during the ensuing weeks or months. However, in a small percentage of patients, wall motion abnormalities may persist for 1 year. Follow-up in various series has shown recovery of left ventricular ejection fraction to normal in most instances. In-hospital mortality in larger series has been reported at 0% to 4%.^{72,74–76,79,80} The large majority of survivors will recover completely with normal functional status. The long-term prognosis is good. In one series, only 2 out of 72 patients had recurrence of TABS within 13 months.⁷⁴ In another series, the recurrence of TABS was calculated at 2.9% per year. Over a 4-year follow-up, long-term survival of patients who recovered from TABS was equivalent to sex- and age-matched control groups without a history of TABS.⁸⁰

The pathogenesis of TABS is unknown. Transient multivessel coronary spasm has been proposed, but this has not been demonstrated at the time of acute coronary angiography in the vast majority of patients. In most patients, the extent of left ventricular wall motion abnormality

is larger than the distribution of a single coronary artery.^{72,73} Cardiac MRI has not shown evidence of infarction or myocarditis.⁸¹ In our judgment, a hyperadrenergic state, precipitated by acute stress and causing myocardial stunning, is the most attractive hypothesis. One study documented supraphysiologic levels of serum catecholamines and stress neuropeptides in patients during the acute phase of TABS, likely due to adrenal and sympathoneuronal hyperactivity. The apex of the left ventricle may be more sensitive than other left ventricular wall segments to the deleterious effects of adrenergic hyperstimulation.⁷⁵

TABS is reported to occur in approximately 1.7% to 2.2% of admissions for acute coronary syndrome in Japan and 2% of cases of acute heart failure due to acute coronary syndrome.^{79,81} TABS may be more common than currently recognized. Correct diagnosis is more likely to be made in centers where emergency coronary angiography and primary percutaneous coronary intervention are used in the treatment of acute coronary syndrome and ST-segment elevation myocardial infarction.

In summary, TABS should be suspected in patients who present with symptoms and ECG findings consistent with acute myocardial infarction, who have a large apical wall motion abnormality seen on echocardiography or left ventriculography and whose symptoms were precipitated by severe emotional or physical stress. Diagnosis is confirmed when urgent cardiac catheterization and coronary angiography demonstrate no significant coronary artery occlusion or stenosis.

TACHYCARDIA-INDUCED CARDIOMYOPATHY

A sustained rapid heart rate can lead to the acute development of left ventricular dilation and dysfunction, with symptoms of heart failure. This is termed *tachycardia-induced cardiomyopathy* (TICMP). This can occur in otherwise normal hearts or can exacerbate heart failure in patients with preexisting cardiomyopathy. Supraventricular or ventricular arrhythmias of any type can lead to this syndrome. Arrhythmias that may be responsible for TICMP include atrial fibrillation, atrial flutter, automatic atrial tachycardia, AV node reentry tachycardia, supraventricular tachycardia involving accessory pathways, accelerated junctional tachycardia, ventricular tachycardia (from RV and LV sites), sustained rapid cardiac pacing, and even very frequent premature ventricular contractions and prolonged, sustained ventricular bigeminy.

The development of TICMP is related to the rate of the tachycardia as well as the duration of the arrhythmia and the presence of other cardiac conditions.⁸² The length of time tachycardia needs to be present to cause LV dysfunction is unknown, but sustained arrhythmia for days to weeks is likely necessary. The presence of an underlying predisposing substrate has been postulated, as not all patients with sustained tachycardia will develop cardiomyopathy.⁸³

Animal models of TICMP have been established and studied to elucidate pathophysiologic mechanisms and clinical correlates. In these models, sustained, rapid atrial or ventricular pacing leads to severe biventricular systolic and diastolic dysfunction with four-chamber dilation and to changes in LV geometry to a more spherical shape. Within 24 hours of initiating rapid pacing, there is a fall in cardiac output and blood pressure. During the first week, pulmonary artery pressure rises and there is an increase in left and right ventricular filling pressures. Neurohormonal activation occurs as typical for dilated cardiomyopathy. The cardiac output and ejection fraction fall, and the ventricular volume rises over 3 to 5 weeks. When pacing is discontinued, cardiac output improves to near normal in 48 hours, and hemodynamics are normal within 4 weeks. The ejection fraction recovers to normal in 1 to 2 weeks, although the end-diastolic volume remains high at 12 weeks, suggesting persistent remodeling. Structural cardiac changes seen include myocyte hypertrophy, apoptosis, and altered extracellular matrix. Proposed pathophysiologic mechanisms include myocardial energy depletion, ischemia, and altered myocyte handling of calcium.^{83,84,85,86}

At present, there are no data regarding the time course, mechanisms, or cellular biochemical alterations in human TICMP. TICMP can occur at any age, from infants to the elderly. TICMP has been reported to occur in fetuses with sustained supraventricular tachycardia, which resolves with correction of the arrhythmia.⁸⁴ Whether a minimal heart rate is necessary to induce cardiomyopathy is unknown. The incidence and prevalence of TICMP are also unknown. One study analyzed patients who were hospitalized for treatment of heart failure who had rapid atrial fibrillation and no prior diagnosis of cardiac illness. One-third of this group was determined to have TICMP. These patients had smaller ventricles initially and had a better long-term prognosis, with lower rehospitalization and mortality rates.⁸⁷ In other observations, patients with rapid atrial fibrillation and cardiomyopathy treated with AV node ablation also show improved cardiac function over time, indicating that the tachycardia was more important than the lack of atrioventricular synchrony in the pathophysiology of cardiomyopathy.

The diagnosis of TICMP should be suspected in any patient with impaired ventricular function in the setting of sustained SVT or VT. The diagnosis is clear when LV function before the onset of tachycardia was demonstrated to be normal and no intercurrent illness other than the arrhythmia has occurred. The diagnosis is confirmed when LV function rapidly improves with correction of the arrhythmia.

The treatment for TICMP is to rapidly restore normal heart rate. This can be done with parenteral rate-slowing medication, including beta-blockers such as esmolol or metoprolol or calcium-channel blockers such as diltiazem. Verapamil may aggravate hypotension and LV dysfunction and should be avoided. Adenosine can rapidly convert AV nodal reentry tachycardia to sinus rhythm. Intravenous digoxin can also be considered, although its onset of action is delayed. Type I drugs such as procainamide can be prescribed for SVT associated with accessory pathways. Electrical cardioversion can rapidly terminate supraventricular and ventricular tachycardia and restore sinus rhythm. In patients with atrial flutter or atrial fibrillation, reliable control of the heart rate to a range of 60 to 90 beats per minute is a reasonable alternative to conversion of the arrhythmia to sinus rhythm.

In patients with TICMP who have received appropriate arrhythmia therapy, heart failure symptoms improve rapidly. LV systolic function will generally recover to normal within 4 weeks if there is no other underlying heart disease. Cardiac rhythm monitoring for 24 to 48 hours is often necessary to ensure that heart rate is controlled during activity as well as at rest.⁸⁴ In a report of 11 patients with atrial flutter and abnormal systolic function who underwent atrial flutter ablation, ejection fraction improved from an average of 31% at baseline to 41% within 7 months of ablation. Lack of resolution of cardiomyopathy was predicted by a lower baseline ejection fraction.⁸⁸ In a series of 24 patients with TICMP, cardiomyopathy initially resolved with arrhythmia control; recurrence of arrhythmia led to repeated rapid decline in LV function and recurrent heart failure. These patients again had improvement or normalization of ejection fraction following repeated arrhythmia control within 6 months. However, 3 of the patients died suddenly and unexpectedly, emphasizing that structural and electrical abnormalities may persist on a chronic basis.⁸⁹

It is important to recognize that uncontrolled tachycardia may be responsible for causing or exacerbating left ventricular dysfunction and heart failure in many patients. Adequate control of heart rate and, at times, conversion of tachyarrhythmia to sinus rhythm can be the most important therapeutic measures to treat heart failure and initiate reverse remodeling and thus improve LV function in these patients.

KEY POINTS

1. Myocarditis is most often caused by a viral infection. Myocardial damage is mediated through activation of cellular immune processes.
2. The clinical course of myocarditis can be benign, with complete resolution, or the illness can be more severe, with the development of dilated cardiomyopathy and congestive heart failure. Fatal arrhythmia can occur.
3. The pharmacologic therapy of heart failure associated with myocarditis is similar to therapy used in other forms of dilated cardiomyopathy. Severe cases may require the use of mechanical circulatory support.
4. Fulminant myocarditis is an unusual complication with a rapidly progressive course resulting in cardiogenic shock. These cases should be managed aggressively with pharmacologic therapy and circulatory support where required, because significant improvement in left ventricular function will often occur.
5. Endomyocardial biopsy is frequently used to make the diagnosis of myocarditis and to direct therapy, although there are limitations in the interpretation of biopsy results. Newer molecular and histochemical analyses of EMB samples may assist in assessing the cause and treatment of myocarditis.
6. Immunosuppressive therapy based on the results of endomyocardial biopsy should not be used routinely in the treatment of myocarditis but should be strongly considered in patients who have severe heart failure early in the course of the illness, who have clinical characteristics of a treatable form of myocarditis, or whose condition deteriorates despite the use of conventional heart failure treatment.
7. Transient apical ballooning syndrome, or stress cardiomyopathy, is an acute, severe cardiomyopathy often precipitated by emotional or physical stress, with a presentation similar to acute myocardial infarction. The prognosis is generally good after a period of aggressive supportive care.

ACQUIRED AND CONGENITAL HEART DISEASE IN CHILDREN

Cardiac diseases in children cover a wide range of diagnoses, from congenital to acquired and asymptomatic to life-threatening. Knowledge of the pathophysiology and clinical presentation of the most common heart diseases in children is of great importance for those involved in caring for children's health. The aim of this chapter is to highlight the physiologic and developmental aspects of cardiac disease in children and present a brief overview of acquired and congenital pathologies, focusing on common lesions and information of particular importance to intensivists. A detailed overview of all aspects is beyond the scope of this chapter, and readers are directed elsewhere for detailed coverage of pediatric cardiology,^{1,2} pediatric cardiac surgery,³ and pediatric cardiac intensive care.⁴

PHYSIOLOGY

Circulatory Changes at Birth

During the transition from intrauterine to extrauterine life, major circulatory changes occur that have important implications for the clinical care of a newborn.^{5,6} In a healthy newborn, the low-resistance placenta is eliminated from circulation at birth, resulting in an immediate increase in systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) falls when the lungs become responsible for gas exchange. In addition, the fetal channels, foramen ovale, and arterial duct become redundant and close. Failure of the transition from fetal to postnatal circulation results in altered hemodynamics, as seen in babies born with congenital heart disease (CHD) or structurally normal hearts but persistent right-to-left shunt after birth. The circulatory pattern characterized by failure of the PVR to fall is termed *persistent pulmonary hypertension of the newborn* (PPHN).⁷ PPHN is one of the two principal causes of "nonpulmonary" cyanosis in neonates, the other being cyanotic CHD.

The right ventricle (RV) and left ventricle (LV) contribute equally to fetal cardiac output. At birth, the LV becomes responsible for systemic circulation; it is characterized by its high vascular resistance. The dramatic fall in PVR at birth to 50% of the fetal level facilitates the necessary increase in pulmonary blood flow. During the first 6-8 weeks of life, PVR falls to adult values as the smooth muscle layer in the media of the pulmonary arterioles progressively thins out. The LV progressively adapts to its "high-pressure" role by rapid myocardial growth in contrast to the RV, which regresses to its "low-pressure" subpulmonary role. The presence of CHD can profoundly alter these adaptive processes (see below).

Physiology of the Neonatal Myocardium

The neonatal myocardium is functionally immature⁸ (Table 83-1). Age-dependent changes in intrinsic function and integration with maturing circulation determine its response to insults such as hypoxia and ischemia.⁹

Maturation of the myocardium in the postnatal period occurs through an increase in the number, volume, and conformation of its myocytes. The cell membrane (sarcolemma) develops a T-tubular

system, which facilitates the rapid conduction of action potential to the cell center, and the gradual uniformity of myofibril arrangement improves its contractile function. In parallel with these structural changes, myocellular metabolism matures over time. Proper contractile function of the cardiac myocyte depends on an efficient excitation-contraction process, which is activated by the binding of calcium to troponin C. In the adult heart, calcium release from the sarcoplasmic reticulum is the predominant source of calcium for troponin C activation, whereas in the neonate heart, activation relies substantially on calcium influx through the L-type calcium channels. Optimal function of the neonatal myocardium is therefore exquisitely dependent on the maintenance of normal extracellular calcium concentrations. Other elements of myocyte function are age-dependent, such as the sarcoplasmic reticulum calcium-ATPase, which is present in reduced quantities in the immature heart. This results in relatively inefficient calcium reuptake and therefore slower diastolic relaxation, which is, at least in part, responsible for the prominence of diastolic dysfunction in the failing neonatal myocardium.

Healthy infants have higher plasma concentrations of catecholamines and higher density of cardiac sympathetic innervation than older children and adults. This may partly explain the reduced ability of neonates to increase cardiac output in response to endogenous or exogenous catecholamines. Children with heart failure also have higher plasma catecholamine concentrations¹⁰ but reduced beta adrenergic receptor densities than age-matched controls.¹¹ The effects of this are similar to those seen with exogenous agonist-induced desensitization. Children with severe heart failure show evidence of uncoupling of beta1 adrenergic receptors from the enzyme adenylyl cyclase¹¹ and other maladaptive responses, which result in a reduced response to receptor agonists. In addition to heart failure, chronic hypoxia as seen in cyanotic CHD induces activation of the sympathetic nervous system with resultant adrenergic receptor desensitization. Developmental aspects of myocardial support have been reviewed.¹²

Congestive Heart Failure

Although the basic pathophysiologic mechanisms of heart failure are age-independent, the presentation and management of heart failure change with age. The overwhelming cause of heart failure in the first year of life is CHD, usually with an intracardiac left-to-right shunt or a ventricular obstructive lesion (Table 83-2). By contrast, the primary abnormality in adult heart failure is usually LV dysfunction. Heart failure in adults is often gradual in onset, whereas the limited functional reserve in neonates leads to rapid decompensation and an emergent presentation.

The clinical findings² in an infant are listed in Box 83-1. A prominent sign of cardiac failure in infancy is difficulty in feeding secondary to an increased respiratory rate and effort. This equates to exertional dyspnea in an older child or adult. This results in failure to thrive and leads to the classic "wizened" appearance. Although hepatomegaly is a common sign of heart failure in infants (resulting from an increase in total circulating volume and hepatic venous congestion), peripheral edema, ascites, and pericardial or pleural effusions are much less commonly seen in infants than in adults. One relatively common feature of severe heart failure in infancy is the occurrence of compression of the bronchial tree, particularly the left main stem or lower lobe

TABLE 83-1 Characteristics of the Neonatal Ventricle

| COMPARISON TO MATURE VENTRICLE | |
|--------------------------------|---|
| Contractility | Contractility of the neonatal ventricle is reduced. |
| Compliance | Neonatal ventricle inherently noncompliant. |
| Augmentation cardiac output | Little stroke volume reserve due to low compliance. Therefore cardiac output is highly heart rate dependent in neonates. |
| Afterload | Neonatal ventricle tolerates poorly increased afterload. |
| Energy substrate | Lactate primary substrate of neonatal ventricle under aerobic conditions. Glucose metabolized under anaerobic conditions. By 1-2 years changeover to primary “adult” substrate, free fatty acids. |

TABLE 83-2 Common Causes of Heart Failure in Childhood

| NEONATE <2 WEEKS OF AGE | NEONATE >2 WEEKS OF AGE, INFANT | OLDER CHILD |

| Hepatomegaly |
| Cardiomegaly |
| Poor peripheral perfusion—in severe failure “ashen” appearance |

bronchus as a result of extrinsic compression by an enlarged left atrium (LA) or pulmonary artery (PA). This can cause airway obstruction and associated lobar collapse or localized hyperinflation as a result of distal air trapping. Long-standing extrinsic compression may rarely cause tracheobronchomalacia, resulting in long-term respiratory difficulties even after the resolution of heart failure.

Cyanosis

Cyanosis is the visible manifestation of greater than 5 g/dL of reduced deoxygenated hemoglobin in cutaneous blood vessels and is a prominent feature in many types of CHD. *Peripheral cyanosis* results from high oxygen extraction ratios across the tissue vascular bed, reflecting low tissue blood flow, or a high tissue oxygen demand. *Central cyanosis* results from the desaturation of arterial blood, which may be due to pulmonary disease or the right-to-left shunting of deoxygenated systemic venous blood in association with a congenital heart defect. The “pulmonary” and “cardiac” causes of central cyanosis can usually be differentiated by allowing the child to breathe 100% oxygen (“hyperoxic test”), which results in a substantial improvement in oxygen saturation in case of cyanosis of pulmonary origin, while having little effect on a child with cyanosis due to a right-to-left shunt.¹³ During the administration of 100% oxygen an arterial oxygen tension (PaO₂) above 160 mm Hg is highly suggestive of a noncardiac diagnosis, and a PaO₂ greater than 250 mm Hg excludes it. Occasionally, *differential cyanosis* is seen, where one or both upper limbs are normally saturated and the lower limbs cyanosed. This is caused by deoxygenated blood traversing the arterial duct to enter the aorta distal to the origin of one or both subclavian arteries and supply the lower limbs, while oxygenated blood from the LV predominantly supplies the upper limbs.

Chronic hypoxemia induces twin physiologic responses of erythropoiesis, resulting in polycythemia and an increase in blood volume as a compensatory attempt to maintain oxygen carrying capacity. However, as hemoglobin concentrations rise, blood viscosity increases and ultimately results in sluggish flow in peripheral circulation, cellular aggregation, and occurrence of thrombotic lesions. Polycythemic patients are at a high risk of thrombotic complications in situations of increased fluid loss (e.g., intercurrent diarrheal illness) or inadequate fluid intake (e.g., preoperative fasting). In addition, most children with chronic cyanosis develop finger clubbing as a result of an increased number of capillaries laid down in the vascular beds of the fingers and toes. Rare, but important, complications of severe cyanosis arise primarily from hypoxemia and polycythemia and include cerebral and pulmonary thrombosis and cerebral abscess.

Pulmonary Vasculature and Pulmonary Hypertension¹⁴

The pulmonary vascular bed is of central importance to the manifestation of CHD from the first hours of life. As previously described, PVR falls dramatically at birth and reaches adult values by approximately 2 months of age. In infants with congenital heart lesions where intracardiac communication occurs between systemic and pulmonary circulations such as a ventricular septal defect (VSD), the fall in PVR encourages flow into the low-resistance pulmonary vascular bed, and a left-to-right shunt develops. The increased flow and subsequent shear stress induce progressive structural changes in the pulmonary arteries and arterioles. Initially, these changes consist of accelerated extension of muscle to the distal “nonmuscular” pulmonary arteries and medial muscular hypertrophy in the proximal muscular arteries. Later changes involve gradual hypertrophy of the arterial intima with the deposition of collagen and elastin, leading to gradual luminal obstruction and eventual occlusion. Associated with this is the development of plexiform lesions, the histologic hallmark of pulmonary vascular disease. Mild pulmonary vascular changes are of little significance to cardiac intensivists; however, children with more extensive medial muscular hypertrophy of the pulmonary arteries are at a risk of labile pulmonary pressure, leading to pulmonary hypertension (PHT) in the postoperative period (see below). The extent of pulmonary pressure changes—that is, hypertension—frequently determines the feasibility of surgical options. Children with established fixed high PVR are not suitable for undergoing corrective surgery, as the surgical separation of the two circulations in the face of fixed high PVR will result in immediate RV failure. Smaller elevations in PVR determine operability in the single ventricle “Fontan” circulation (see Complex Single Ventricle

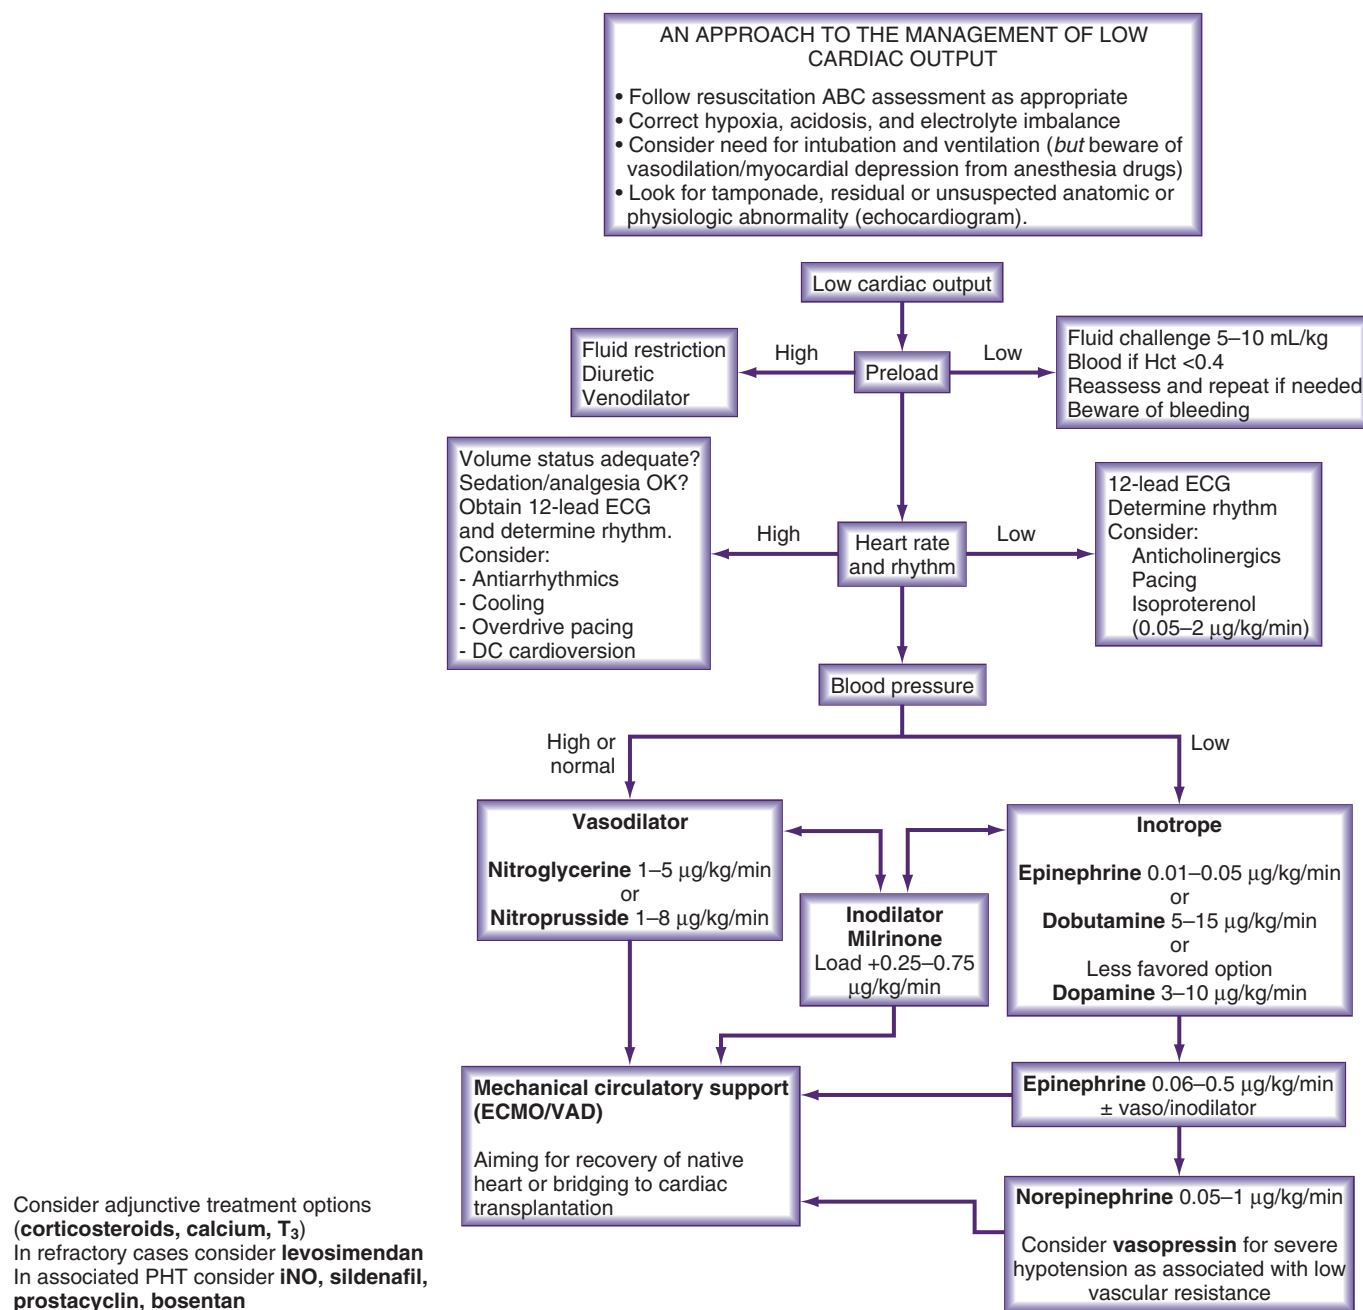

FIGURE 83-1 ■ Management of low cardiac output in children.

Circulations). The calculation of PVR and the response to varying vasodilators can be achieved following a pulmonary reversibility study in a cardiac catheter laboratory.^{15,16}

■ CIRCULATORY SUPPORT IN CHILDREN

Children presenting with circulatory failure must initially be assessed and managed according to standard resuscitation algorithms¹⁷ (Fig. 83-1). These require that an adequate oxygenation and circulating volume be achieved. If cardiac output remains low, cardiovascular drug therapy is usually indicated. Developmental differences noted above serve to emphasize the need to adopt age-appropriate pharmacologic strategies when supporting the failing myocardium of neonates and infants.¹⁸⁻²⁰ If the cardiac output remains low despite the application of such measures, mechanical circulatory support should be considered.

Pharmacologic Support¹²

Beta Adrenergic Agonists

Clinical and experimental studies have demonstrated marked age-related differences in the hemodynamic response to inotropic therapy. Although some of the observed differences may be accounted for by differences in drug pharmacokinetics, the variable maturation of the sympathetic nervous system, its receptors, and the cardiac myocytes mitigate against the recommendation of specific dose ranges for the use of catecholamines in neonates and children.^{12,21}

In clinical practice, the use of adrenergic agonists in children is in a titrating manner, which is similar to that in adult practice. When systolic ventricular function is impaired, low-dose epinephrine is commonly used as the first-line inotrope, although dobutamine and dopamine still have their advocates. Dopamine was formerly

preeminent but is now less favored as a result of its noncardiac adverse effects.²² Additional agents should be administered according to the assessment of response judged clinically and from available hemodynamic monitoring. Higher dose epinephrine, norepinephrine, or an alternative class of vasoconstrictors such as vasopressin (see below) can be used in refractory circulatory failure, particularly if vasodilatation is present, which occurs occasionally after cardiopulmonary bypass (CPB) in children. Isoproterenol is a nonspecific beta adrenergic agonist whose principal cardiovascular effects are vasodilatation and increasing the heart rate. The drug is rarely used in intensive care except as a chronotropic agent when the heart rate is critically low and cardiac pacing is not yet established. Caution is needed when higher dose catecholamine support is used in neonates, as these can induce a rise in ventricular end-diastolic pressure in a ventricle that is already developmentally noncompliant. Catecholamine-induced myocardial necrosis has been identified in neonatal animal models.^{23,24} All adrenergic agonists should be administered cautiously at higher doses as they may have deleterious effects on the failing myocardium, increasing heart rate, and SVR, resulting in increased myocardial oxygen consumption.

Phosphodiesterase III Inhibitors

Phosphodiesterase (PDE) III inhibitors have emerged as important agents in the management of neonates and children with cardiac failure due to both inotropic and vasodilator properties. The cardiovascular actions of the clinically available PDEIII inhibitors—e.g., amrinone, milrinone,²⁵ and enoximone—are similar, although milrinone is the most commonly used drug in children. By inhibiting the breakdown of cyclic adenosine monophosphate (cAMP), intracellular calcium accumulation is promoted, thus augmenting the contractile state of the myocyte. In addition, calcium reuptake, a cAMP-dependent process, is augmented, which may enhance diastolic relaxation, a particularly important aspect of neonatal cardiac function. In a multicenter randomized controlled study of neonates and young children following cardiac surgery, the prophylactic administration of milrinone resulted in a lower incidence of low cardiac output.²⁶ Clinical studies in infants and children have demonstrated a synergistic effect when beta1 agonists and PDE III inhibitors such as amrinone, milrinone, or enoximone are coadministered and that this effect may be greater in neonates than in adults. In clinical use, the prominent vasodilating action of PDE III inhibitors is a useful property given the usual low cardiac output associated with rising SVR and PVR, which has been well documented in young patients following cardiac surgery.²⁷ Milrinone is widely used in the initial management of low cardiac output syndrome associated with elevated SVR following heart surgery in children.²⁸

Vasopressin

The arginine-vasopressin hormone is an alternative to alpha adrenergic vasoconstrictors in the management of refractory hypotension associated with vasodilation in sepsis or following CPB, a situation where endogenous vasopressin might be deficient.²⁹⁻³¹ Vasopressin acts directly at vasopressin V1 receptors on vascular smooth muscle without direct effects on the myocardium or cardiac conduction system.

Systemic Vasodilators

This drug class is useful in situations where lowering SVR will reduce LV afterload and improve cardiac output (Table 83-3). This is particularly important in neonates where the elevation of SVR is poorly tolerated by the immature neonatal myocardium. Vasodilators are also employed in the management of systemic hypertension following the repair of aortic coarctation or other left-sided obstructive lesions. Vasodilators have variable effects on preload through concomitant venodilatation, the manifestations of which are dependent on the position that the resultant end-diastolic pressure occupies on the ventricular function curve. If preload reduction brings the resultant end-diastolic pressure to the preplateau sloping portion of the

ventricular function curve, stroke volume can only be maintained or augmented if the preload is optimized by appropriate fluid administration. Directly placed left atrial pressure monitoring lines are commonly used to determine systemic ventricular loading conditions in neonates. Systemic vasodilators should be used with extreme caution in patients with systemic hypotension and LV outflow tract (LVOT) obstruction since they are at risk of severe systemic hypotension and myocardial ischemia.

In children, sodium nitroprusside is frequently the systemic vasodilator of choice because of its powerful arteriolar dilating properties and short half-life, which render it both effective and highly titratable. Nitroglycerine is an alternative short-acting drug, which acts as an arteriolar dilator at higher doses, but is an effective venodilator at lower doses. Phenoxybenzamine, a long-acting alpha adrenergic blocker, is used in some centers in children undergoing surgery for CHD.^{32,33}

Beyond the acute phase of therapy and when enteral drugs can be reliably administered, angiotensin-converting enzyme (ACE) inhibitors such as captopril and enalapril are used.³⁴ They have peripheral vascular and neurohormonal effects as well as direct effects on the myocardium through the activation of intracellular signaling pathways involved in the growth and apoptosis of cardiac myocytes and fibroblasts. Studies in adults have established that ACE inhibitors improve survival and symptoms in heart failure due, in part, to favorable effects on cardiac remodeling. Evidence for the use of ACE inhibitors in children is much less clear. Acute hemodynamic benefits have been demonstrated in children with heart failure caused by left-to-right shunts or mitral/aortic insufficiency and systolic dysfunction of the systemic ventricle. Prolonged treatment with ACE inhibitors has been shown to be effective in reducing not only LV volume overload but also LV hypertrophy in the hearts of growing children with chronic LV volume overload.^{35,36} However, a multicenter randomized controlled trial of ACE inhibitors and placebo showed no difference on somatic growth, ventricular function, or severity of heart failure with enalapril administration to infants with a single ventricle during the first year of life.³⁷ Children with heart disease secondary to muscle disease—that is, Duchenne cardiomyopathy (CM)—may benefit from ACE inhibitors as it seems to delay the progression of heart disease.³⁸ ACE inhibitors should be avoided in patients with left heart obstruction.

Digoxin

Digoxin may have weak inotropic actions through its inhibitory effect on Na/K ATPase and may also have peripheral effects that attenuate the actions of the neurohormonal system. Several studies in adults have shown that digoxin improves symptoms in heart failure.³⁹ Although no studies have shown survival improvement,^{39,40} there is a resurgence of interest in defining the role of digoxin in the management of heart failure. Digoxin is widely used to treat heart failure in children, although as in adults, there are insufficient data that support or refute its use.²⁰ It has been recommended as an alternative drug for symptomatic heart failure and low ejection fraction with careful serum level monitoring, especially when combined with carvedilol or amiodarone and in patients at risk of renal dysfunction.⁴¹

Diuretics

The use of diuretics is ubiquitous in the treatment of children with heart failure,²⁰ with the main goal of improving symptoms of pulmonary congestion. There are no pediatric studies showing that diuretic therapy in heart failure reduces morbidity or mortality, although fluid overload following cardiac surgery has been suggested to be associated with poor outcomes.⁴²⁻⁴⁴ Furosemide is the most widely used diuretic in pediatric cardiac care.⁴⁵ While intravenous bolus administration of furosemide is preferred to oral administration in acute situations, studies have shown that continuous infusion leads to a smoother control of fluid and electrolyte shifts than intermittent IV bolus administration.⁴⁵ Potassium-sparing diuretics such as spironolactone are also widely used adjunct to therapy with furosemide, particularly in

TABLE 83-3 Vasoactive Agents in Children

| ADRENERGIC AGONISTS | | | | | | |
|----------------------------|---|---|----------------|---------------|----------|---|
| | INTRAVENOUS DOSE RANGE | ALPHA 1 | BETA 1 | BETA 2 | DOPA | COMMENTS |
| DOPAMINE | 1-5 µg/kg/min 5-15 µg/kg/min | 0 0/++ | +/++ ++ | | ++ ++ | Beta-mediated inotropic effects at lower doses. Alpha-mediated vasoconstriction at higher doses |
| DOBUTAMINE | 2-15 µg/kg/min | 0 | +/+++ | 0/++ | 0 | |
| EPINEPHRINE | 0.01-0.1 µg/kg/min 0.2-0.5 µg/kg/min | 0/++ ++/+++ | ++/+++ ++++ | ++/+++ +++ | 0 0 | Beta-2 effect prominent at lower doses. Alpha constrictor effects at higher doses |
| NOREPINEPHRINE | 0.05-0.5 µg/kg/min | ++/++++ | + | 0 | 0 | Increases SVR. Reserved for treatment of severe hypotension associated with vasodilatation |
| ISOPROTERENOL | 0.02-0.4 µg/kg/min | 0 | ++++ | ++++ | 0 | Prominent chronotropic activity. Beta-2 effects cause vasodilatation |
| OTHER CARDIOVASCULAR DRUGS | | | | | | |
| | DOSAGE | EFFECTS | | | | |
| Amrinone | Neonates: 4 mg/kg over 15 minutes, then 3-5 µg/kg/min IV >4 weeks age: 1-3 mg/kg over 30 minutes, then 5-15 µg/kg/min IV | Cardiac: Mild nonadrenergic inotropic and lusitropic effects Vascular: Systemic and pulmonary vasodilator | | | | |
| Milrinone | All ages: 50-75 µg/kg over 20 minutes Maintenance: 0.25-0.75 µg/kg/min IV | May cause thrombocytopenia Reduce amrinone dose in slow acetylators Reduce milrinone dose in renal failure Duration of effect, 3-7 days | | | | |
| Levosimendan | 0.05-0.2 µg/kg/min IV for 24 hours | | | | | |
| DIGOXIN | Initial dose: 15 µg/kg, then 5 µg/kg after 6 hours Thereafter 5 µg/kg 12 hourly. Slow IV or oral. | Delays AV conduction, used in management of supraventricular tachycardia Mild inotropic properties. May provide symptomatic relief in congestive heart failure Bradycardia, supraventricular or ventricular dysrhythmias in overdose Aim for plasma level 0.8-2.0 ng/mL Dose adjustment required in renal failure | | | | |
| ESMOLOL | Short-term management of SVT and perioperative hypertension 5-200 µg/kg/min IV | Bradycardia Hypotension Bronchospasm | | | | |
| NITROPRUSSIDE | 0.5-8 µg/kg/min IV Direct blood pressure monitoring required | Systemic and pulmonary vasodilatation Systemic hypotension prominent Cyanide toxicity <ul style="list-style-type: none"> • Metabolic acidosis earliest sign • Monitor thiocyanate levels when used >48 hours or in renal failure | | | | |
| CAPTAPRIL | Oral administration: 0.05 mg/kg as a test dose, then incremental increases to 0.4 mg/kg (occasionally up to 1.0 mg/kg), titrated to effect (systemic blood pressure). 8 hourly dosing. | Systemic vasodilatation/hypotension Small increase in plasma potassium levels | | | | |
| NITROGLYCERIN | 0.2-8 µg/kg/min IV Direct blood pressure monitoring required | Systemic and pulmonary vasodilatation | | | | |
| PROPRANOLOL | Relief of RV spasmodic RV outflow obstruction in the emergency management of hypercyanotic spells in tetralogy of Fallot 0.05-0.1 mg/kg IV stat Systemic hypertension 2-6 mg/kg in 4-6 divided doses | Bradycardia Hypotension Bronchospasm Lethargy | | | | |

long-term therapy. Although dopamine has a natriuretic effect, there is no evidence to support the use of dopamine for prevention or treatment of renal impairment.

Beta-Blockers

Although beta-blockers have an established role in the management of heart failure in adults, evidence of benefits in children with heart failure is limited and based on small studies.^{34,46-49} A recent publication has suggested that the benefit of adding beta-blockers to ACE inhibitors is minimal.⁵⁰ While it might be reasonable to extrapolate adult survival advantages to older children and adolescents with heart failure, extreme caution should be exercised in seeking to apply such therapy in younger children and neonates, as there may be differences among age groups regarding genetics, pharmacology, and underlying

causes of heart failure.⁵¹ Furthermore, beta-blockers should always be introduced with extreme caution in patients with heart failure. Beta-blockers have an established role in children in the management of hypertension and ventricular outflow tract obstruction such as that which occurs in tetralogy of Fallot.

Levosimendan

Levosimendan offers a new therapeutic adjunct in the management of patients with severe ventricular dysfunction by enhancing cardiac contractility and vasodilatation without affecting intracellular free calcium.⁵² The drug acts by enhancing the sensitivity of cardiac myofilaments to calcium. Levosimendan is a prodrug acting mainly through its active metabolite, which has a long elimination half-life with effects lasting for up to 7 to 9 days after a single dose, a sharp

contrast to intravenous catechol-based inotropes with extremely short half-lives. The myocardial effects of levosimendan show improvement not only in systolic function but also in improved diastolic function, which is significantly impaired in those with severe heart failure. One of the problems in understanding the clinical utility of levosimendan has been to quantify the magnitude of its lusitropic effects, separating it from inotropic and chronotropic effects. Jorgensen et al.⁵³ published a study of the use of levosimendan in a carefully monitored group of adult patients with aortic valve disease. They demonstrated unequivocally that levosimendan exerts a direct positive lusitropic effect, shortening isovolemic relaxation time and improving LV filling.

There is increasing interest in the use of levosimendan in children.⁵⁴⁻⁵⁶ A randomized double-blind controlled clinical trial of levosimendan administration following pediatric cardiac surgery showed it to be at least as effective as milrinone, with the levosimendan group having significantly lower myocardial oxygen demand.⁵⁷ Some authors have suggested using levosimendan on a rotating inotrope therapy for children with decompensated heart failure.⁵⁸ More substantial clinical trials are still needed to support the use of levosimendan as a routine inotrope after cardiac surgery and in heart failure.

Thyroid Hormone

Thyroid hormones (triiodothyronine-T3 and thyroxine-T4) play an important role in the regulation of heart metabolism,⁵⁹ upregulation of beta adrenoceptors, and increasing cardiac myocyte contractility.⁶⁰ Critical illness can be associated with inappropriately normal or suppressed TSH levels, despite low T3 levels, the so-called nonthyroidal illness or sick euthyroid syndrome. This can occur in children after CPB,⁶¹⁻⁶³ and its importance is disputed, although clinical studies have shown that T3 supplementation can produce elevation in the heart rate without a concomitant decrease in systemic blood pressure⁶⁴ and may enhance cardiac function reserve in infants after CPB. In a double-blind placebo-controlled trial of T3 supplementation in children <2 years of age undergoing CPB, although some indices of cardiac function assessed by echocardiography were judged to be better in the T3 group, no significant differences were found in the clinical endpoint of time to extubation in the entire study population.⁶⁵ Further age-stratified analysis showed reduced time to extubation and lower inotropic score among infants younger than 5 months in the T3 group.⁶⁶ Further studies are needed before T3 can be recommended in critically ill children without abnormal thyroid function.

Insulin

The use of tight glycemic control (TGC) to improve outcomes in critical illness remains controversial.⁶⁷ Pediatric randomized controlled trials of TGC that included children following pediatric cardiac surgery, although supportive of the intervention in general pediatric critical care population,^{68,69} have failed to provide evidence for the use of TGC in children following cardiac surgery.^{69,70} A secondary analysis by Agus et al. suggests that TGC in children >60 days of life lowers the risk of infection.⁷¹ The use of TGC after pediatric cardiac surgery is not currently recommended.

Steroids

Steroids are used in the perioperative management of patients undergoing cardiac surgery in some centers, either in association with CPB (pre- or intraoperatively) or postoperatively in relative adrenal insufficiency. CPB is associated with systemic inflammatory response syndrome, and therefore steroids have been prophylactically administered with the aim of preventing or minimizing it.^{72,73} However, the results of pediatric studies of preoperative steroids are open to wide interpretation, and its benefits have been questioned.⁷⁴⁻⁷⁸ Similar to critical illness-related adrenal insufficiency, patients who have undergone CPB may develop absolute or relative adrenal insufficiency, which may precipitate or evolve to low cardiac output syndrome following cardiac surgery. For this reason, steroids have been used in patients with hypotension and signs of adrenal insufficiency post cardiac surgery.⁷⁹

Pulmonary Vasodilators and Other Strategies to Prevent and Treat PHT¹⁴

Oxygen alone is a potent pulmonary vasodilator, with both higher alveolar oxygen concentrations and higher pulmonary arteriolar oxygen saturations lowering PVR. Lung volume also affects PVR, being raised at both low and very high lung volumes. Avoiding atelectasis, alveolar hypoxia, and pulmonary arteriolar hypoxia are simple initial strategies to minimize PVR and PA pressure.

Elevation of PVR, as seen in all children following CPB²⁷ with reactive postoperative pulmonary hypertensive episodes, typically occurs following correction of left-to-right shunt lesions or in those with preoperative pulmonary venous hypertension.⁸⁰ Additional perioperative risk factors for pulmonary hypertensive spells with associated systemic hypotension include long CPB duration and late presentation for surgery. In the current era, early corrective surgery has dramatically reduced the number of infants in whom PHT is a major perioperative issue. Postoperative PHT is still seen in neonates and infants with obstructed total anomalous pulmonary venous drainage, truncus arteriosus, and mitral valve replacement for congenital mitral stenosis. Children with mild to moderate PHT with or without RV dysfunction may also benefit from pulmonary vasodilatation such as following cardiac transplantation⁸¹ and in Fontan circulations,⁸² where low PVR is necessary. General measures directed to the prevention and treatment of PHT should be considered before deploying specific pulmonary vasodilators (Table 83-4). In patients at a high risk of PHT following cardiac surgery, LV filling can be maintained by right-to-left shunting through a small surgically created atrial septal defect (ASD). A right-to-left shunt acts as a safety gradient valve, while tolerating some systemic desaturation, to maintain LV filling and hence cardiac output.

Historically, most IV drugs used to treat PHT had nonselective effects, dilating both the pulmonary and systemic vascular beds, and these include tolazoline, prostaglandin E1, prostacyclin, and nitrodilators. Prostacyclin is a short-acting vasodilator that acts via increasing the levels of the intracellular messenger cAMP and has been widely used in the treatment of primary PHT in children.⁸³ The pulmonary effects of such nonselective agents are frequently limited by their nonspecific action, leading to clinically important systemic hypotension. In contrast, nitrates, sodium nitroprusside, and nitric oxide act via the activation of guanylate cyclase and hence increase cellular levels of cyclic guanosine monophosphate, which is then inactivated by PDE 5.

Nitric oxide is an endogenous endothelial-derived vasodilator and a gas at room temperature. If added to inhaled gas mixtures in children

TABLE 83-4

Strategies to Prevent and Treat Pulmonary Hypertension

| STRATEGY | COMMENT |
|------------------------------------|---|
| Anatomic investigation | Rule out residual or undiagnosed anatomic abnormalities |
| Permit right-to-left decompression | Deliberate residual ASD acts as "pop off" in at-risk situations |
| Analgesia/sedation | Facilitate ventilation. Minimize sympathetic influences |
| Avoid acidosis | Respiratory and metabolic acidosis raises PVR |
| Maintain oxygenation | Normal/high alveolar and mixed venous PO ₂ lowers PVR |
| Optimize hematocrit | Ensures optimal oxygen delivery and higher mixed venous PO ₂ |
| Optimize cardiac output | Ensures optimal oxygen delivery and higher mixed venous PO ₂ |
| Pulmonary vasodilators | Selectively reduce PVR |

with reactive PHT, it induces selective pulmonary vasodilatation.⁸⁴ It is distributed to ventilated alveoli, from where it diffuses into the adjacent pulmonary arteriolar smooth muscle. Inhaled nitric oxide (iNO) has been shown in randomized controlled trials to be an effective and a safe therapy in PPHN. Although the evidence for outcome benefit is drawn mainly from one randomized controlled study,⁸⁵ there is a substantial body of evidence to show that iNO is effective in pediatric cardiac patients including those with acute postoperative PHT following congenital heart surgery^{86,87} and following pediatric heart transplantation. iNO can be used in the preoperative assessment of patients with PHT.^{16,88} A recent metaanalysis of randomized and quasi-randomized controlled trials comparing iNO with placebo or conventional management of PHT in children with CHD after surgery has shown no benefit of iNO in terms of mortality, number of PHT crises, and hemodynamic changes; however, the limited number of studies included and potential biases impede solid conclusions, with the need for further well-designed trials.⁸⁹

Other selective pulmonary vasodilators investigated for use in children include inhaled prostacyclin,^{90,91} the PDE 5 inhibitor sildenafil,⁹²⁻⁹⁵ and bosentan, an endothelin 1 receptor blocker.⁹⁶⁻⁹⁸ Inhaled prostacyclin (iloprost) may be useful for the management of PPHN and children with CHD undergoing cardiac surgery,⁹⁹ but beyond small case series, consistent clinical trials are needed to advocate inhaled prostacyclin administration. The type 5 PDE inhibitor sildenafil is increasingly used in the clinical management of PHT in children. Bosentan seems to have favorable effects in children with PHT and in PPHN,^{100,101} although strong evidence is still lacking.

Mechanical Circulatory Support

Mechanical circulatory support may be lifesaving in cases of severe circulatory failure.¹⁰² The aim of mechanical circulatory support is to provide optimal systemic blood flow; facilitate decompression and “rest” for the heart, thereby facilitating its recovery; or as a bridge to cardiac transplantation. Extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADs) are the two available forms of delivering mechanical circulatory support in children. ECMO is a mature technology that has been used to support over 25,000 neonates with respiratory failure in whom survival rates to hospital discharge of 75% are expected.¹⁰³ Its use in this setting is supported by randomized controlled trials that demonstrate good short- and medium-term outcomes.¹⁰⁴ ECMO has subsequently been used to provide temporary circulatory support in children with intractable circulatory failure (see Chapter 91). The main advantages of ECMO are its ability to provide biventricular support, additional respiratory support, and its ease of emergency initiation; however, its use is limited to days or weeks.¹⁰² VAD usage in children has been facilitated with the development of smaller devices, and VADs have the advantage of use for weeks or months, which is ideal for bridging to transplant in donor-poor environments. Single-center series¹⁰⁵ and collaborative registry figures of ECMO¹⁰³ or VADs for acute postcardiac surgery indications report similar figures of survival to hospital discharge (~40%), in children who were assumed to not survive without mechanical support. Short- and long-term follow-up and outcome rates of ECMO survivors vary among different reports, which should be further explored in future studies.¹⁰⁶ Rapid ECMO deployment has been reported as an effective intervention for the management of cardiac arrest in a pediatric cardiac ICU and cardiac catheter laboratory.¹⁰⁷ Hospital survival figures for CPR-ECMO seem encouraging, with an estimated survival rate of over 40%,¹⁰⁸ but there are weak and controversial data of long-term neurodevelopmental follow-up.¹⁰⁸⁻¹¹⁰

ACQUIRED HEART DISEASE

Cardiomyopathies

The two most common causes of heart failure in children are CHD and CM. CM is a primary or secondary myocardial disease of either known

KEY POINTS

1. The immature myocardium has little functional reserve, tolerating both increased preload and afterload poorly.
2. Cardiac output in neonates is critically dependent on heart rate.
3. A hyperoxic test will usually differentiate cyanosis resulting from intracardiac shunting of deoxygenated blood and that due to intrapulmonary ventilation-perfusion mismatch.
4. Manipulation of the pulmonary circulation, directed to PVR, and the function of the subpulmonary (“right”) ventricle are pivotal in the understanding and, in turn, managing of the divert setting of congenital heart lesions.
5. Systemic vasodilators play a prominent role in balancing “shunted” circulations and in managing heart failure in children.

or unknown cause associated with cardiovascular dysfunction, and it occurs in children and adults of all ages (see Chapter 82). According to its pathophysiology, CM is classified as dilated, hypertrophic, restrictive, or arrhythmogenic ventricular CM. LV myocardium non-compaction has also been recognized as congenital CM.

Nugent et al. reported the incidence of pediatric CM in a 10-year population-based study in Australian children as 1.24 cases per 100,000 children younger than 10 years of age,¹¹¹ a finding remarkably similar to a recently reported U.S. study.¹¹² Of 314 cases of CM reported by Nugent et al., 184/314 (59%) were dilated CM, 80 (25%) were hypertrophic CM, 8 (2.5%) were restrictive CM, and 42 (13%) unclassified, of which 29 (69%) exhibited LV noncompaction. In this study, 20% of CMs were classified as familial, and in 8.9%, specific mitochondrial or metabolic disease etiologically linked to CM was identified. Of the children in Nugent et al.’s study who underwent myocardial biopsy, 40.3% had histologic evidence of lymphocytic myocarditis according to the Dallas criteria,¹¹³ which contrasts with an incidence of lymphocytic myocarditis in studies in adults of only 10%.¹¹⁴

Presentation

Most children with CM present with signs and symptoms of heart failure, including dyspnea, upper abdominal discomfort, nausea, and vomiting. Abdominal symptoms are often misdiagnosed as indicative of gastroenteritis, although an astute clinician will note the absence of diarrhea. It is presumed that these abdominal symptoms result from hepatic congestion and gut edema as a result of right heart failure or ischemia from splanchnic vasoconstriction. In acute-onset dilated CM, a history of an antecedent flu-like illness is strongly suggestive of a diagnosis of myocarditis. Some children with myocarditis follow a fulminant course typified by the rapid onset of cardiogenic shock.^{115,116} In some cases, CM may present with arrhythmia, especially in LV noncompaction and arrhythmogenic CM cases.

According to the type of CM, a chest X-ray in those with acutely presenting CM shows various degrees of cardiomegaly and pulmonary venous congestion, which are usually more prominent in dilated CM. An echocardiogram is possibly the most useful diagnostic tool, usually able to differentiate the CM type and provide short- and long-term follow-up. In dilated CM, echocardiography will reveal left atrial and ventricular dilatation and impaired systolic and diastolic function and often mitral or tricuspid regurgitation. ECG features are mostly non-specific and may include signs of atrial enlargement, ventricular hypertrophy, ST and T wave changes, and arrhythmias. The presence of Q waves suggests an anomalous origin of the left coronary artery from PA (ALCAPA). If ALCAPA cannot be unequivocally excluded by echocardiography, coronary angiography or CT angiography should be performed.

As CM results from a variety of acquired or inherited disorders, the differentiation of secondary (and possibly treatable causes) from the primary form of the disease is of greatest importance. Vitamin deficiency, viral and bacterial infections, autoimmune disorders, and genetic and metabolic causes should therefore be investigated. Endomyocardial biopsies can be obtained to assist in the diagnosis of myocarditis and other specific myocardial diseases.

Prognosis

Recent studies have reported 5-year survival rates in childhood CM of between 64% and 84%, although the impact of cardiac transplantation on survival rates is not clear in all studies. In contrast to myocarditis, sudden death is uncommon in children with other forms of dilated CM but may be the initial presentation in arrhythmogenic and LV noncompaction CM. Children with CM who fail to respond to conservative treatment and especially those with ongoing requirement for intravenous inotropic support, ventilatory support, or mechanical circulatory support and children with recurrent arrhythmias are candidates for early cardiac transplantation.¹¹⁷ Late recovery of ventricular function is, however, possible.¹¹⁸ The prognosis for CM due to myocarditis in children appears to differ from that in adults, with survival of up to 80% among children who reach the hospital alive.^{119,120} Many children who survive the acute phase recover normal cardiac function in marked contrast to adults, with mortality rates of 20% at 1 year and increasing to 56% at 5 years.¹¹⁴

ICU Management of Decompensated CM

In children presenting with acute heart failure, hypotension, or cardiogenic shock, beta adrenergic agonists may improve systolic ventricular function, especially for those with dilated CM and myocarditis. However, according to the clinical status and dose administered, the inotropic and chronotropic effects of beta adrenergic agonists can increase the diastolic dysfunction further, which is usually seen in patients with hypertrophic CM. In this type of CM, excessive tachycardia is poorly tolerated by the hypertrophied ventricle, and perhaps cautious introduction of beta-blockers at an early stage could be considered as this facilitates diastolic filling. PDE III inhibitors such as milrinone have hemodynamic benefits in acute heart failure (either dilated or hypertrophic CM), improving both systolic and diastolic dysfunction. There are relatively insufficient data to support the use of pure systemic vasodilators in the ICU management of acute heart failure in children. Beta-blockers such as metoprolol and carvedilol may be of benefit in chronic heart failure,^{34,46,47} but they should be avoided in hemodynamically unstable children as should ACE inhibitors. Children with pulmonary venous congestion and pulmonary edema will benefit from diuretics. However, in decompensated hypertrophic CM, adequate ventricular filling is required, and therefore, diuretics should be cautiously administered to avoid hypovolemia.

Nasal or mask continuous positive airway pressure has been shown to result in symptomatic improvement by the unloading of respiratory muscles and lowering of LV afterload as a consequence of raising the intrathoracic pressure.¹²¹ Children with severe heart failure have a high SVR and no ventricular reserve. Great care is therefore needed if sedative agents are administered to facilitate tracheal intubation or ICU procedures. Agents with the fewest effects on the cardiovascular system should be chosen, and an allowance should be made for slow circulatory times when titrating sedative doses.

Anticoagulation may be considered in children with severe cardiac dysfunction. In cases where acute myocarditis is suspected, intravenous immunoglobulin is commonly used, despite the lack of strong evidence to support or refute this practice. Until treatable deficiencies can be ruled out as a cause of CM from the evidence of normal pretreatment blood levels, high-dose vitamin D, carnitine, and coenzyme Q10 should be administered.

The use of mechanical circulatory support with ECMO or VADs can be lifesaving in children with myocarditis or CM who develop

cardiogenic shock.^{122,123} Among neonates and children who require ECMO due to cardiac failure, those with underlying CM and myocarditis have better survival rates than those with other causes of cardiac failure.¹⁰³ A high proportion of children who receive mechanical support for fulminant myocarditis will recover ventricular function. Those who do not recover may be bridged to cardiac transplantation. Clearly, survival with a recovered native ventricle is a better outcome for a child than survival via cardiac transplantation. A multicenter series¹²⁰ documented a median time to return of ventricular function of 9 days in those who survived without transplantation. The absolute time limits for the recovery of native ventricular function have not been established, although pragmatic decisions on whether to proceed to cardiac transplantation should probably be made if cardiac recovery has not occurred after 10 to 14 days of support.¹²⁴

KEY POINTS

1. Mechanical circulatory support is effective in bridging many children with severe heart failure to recovery or cardiac transplantation
2. In the era of mechanical circulatory support, acute fulminant myocarditis in children should be regarded as a recoverable condition.

CONGENITAL HEART DISEASE

CHD, classified as moderate or severe, is detected in approximately 6/1000 live births, of whom between 2.5 and 3 will require expert cardiologic care soon after birth. The presence of extracardiac anomalies in children with CHD is associated with poorer outcomes. Syndromes associated with cardiovascular involvement are of particular significance to pediatric intensivists who must coordinate the cardiac and extracardiac aspects of care.¹²⁵ Trisomy 21 (Down syndrome) is associated with a high incidence of CHD—in particular, atrioventricular septal defects (AVSDs). Deletion of the q11 region of chromosome 22 is associated with a spectrum of cardiac (conotruncal defects, e.g., truncus arteriosus, tetralogy of Fallot) and extracardiac abnormalities.¹²⁶ Of the latter, thymic aplasia places infants at risk of impaired cellular immunity and hypocalcemia secondary to hypoparathyroidism.

Many classifications of congenital heart lesions have been proposed. While a sequential approach to the description of cardiac anatomy is most frequently employed by pediatric cardiologists, a broader physiologic approach is more useful to intensivists.

Lesions with Predominant Left-to-Right Shunt

VSD is the archetypal lesion associated with left-to-right shunting of blood. ASDs, AVSDs, patent ductus arteriosus (PDA), and truncus arteriosus are also lesions with left-to-right shunt. Ventricular output will follow the path of least resistance, resulting in blood shunting across the defect and into the lungs as PVR is lower than SVR. The magnitude of the shunt, usually expressed as the ratio of pulmonary blood flow to systemic blood flow ($Q_p:Q_s$), depends on the size of the defect and the level of PVR. If the defect has a small diameter, it offers resistance at its level, limiting flow from the left-to-right chambers and maintaining a pressure gradient between them. Larger diameter defects are unrestrictive, with no pressure gradient between right and left chambers, and in this situation, flow is solely dependent on the ratio of PVR to SVR—the lower the PVR, the greater will be the shunt and pulmonary blood flow.

Small restrictive defects rarely result in symptoms in infancy, typically presenting when a cardiac murmur is detected as an incidental finding. Infants with larger unrestrictive defects gradually develop congestive cardiac failure due to the increase in pulmonary blood flow, which occurs as PVR falls in the first weeks of life.¹²⁷ Thus, the

consequences of a moderate or large unrestrictive defect are increased pulmonary blood flow (high Qp : Qs) and extra volume work demanded of the LV. The volume overload of the LV results in LV enlargement and failure. If large left-to-right shunts are left untreated, PVR gradually rises. Although the initial rise is the result of pulmonary arteriolar muscular hypertrophy, which is reversible, irreversible pulmonary vascular obstructive disease¹²⁸ eventually ensues, resulting in PA pressure and vascular resistance that exceeds that of the systemic circulation and leads to shunt reversal (right-to-left) and cyanosis (Eisenmenger syndrome). For this reason, steps must be taken in all children with congenital heart lesions and raised pulmonary blood flow to correct the lesion or protect the lungs by either a corrective procedure or a palliative procedure such as PA banding before severe pulmonary vascular changes develop. With the exception of isolated atrial septal defects, most L-R shunt lesions that require surgical intervention present in the first year of life with heart failure and are associated with development of PHT. The principal lesions are described below.

Ventricular Septal Defect

Anatomy. VSD can occur in any part of the interventricular septum and is classified by location,^{129,130} the most common being perimembranous VSD. It may be present in isolation or in association with other cardiac anomalies.

Pathophysiology. Left-to-right shunting at the ventricular level is determined by the defect size and PVR and leads to increased pulmonary blood flow, LA dilatation, and LV volume overload.

Many small VSDs close spontaneously,¹³¹ but if closure does not occur or if the defect is unrestrictive infants will fail to thrive and develop congestive heart failure as PVR falls in early infancy. Untreated VSD leads to PHT and eventual progression to fixed pulmonary vascular obstructive disease and ultimately Eisenmenger syndrome. Patients with a fixed high PVR are not suitable for VSD closure since the RV will not tolerate the excessive afterload of the hypertensive pulmonary vascular bed.

VSD Closure. Most VSDs are repaired as a primary surgical procedure,¹³² with closure performed with a sutured patch during CPB. Alternatively some defects may be closed with an occlusion device at cardiac catheterization.¹³³ Occasionally, PA banding is undertaken to reduce pulmonary blood flow and protect the pulmonary vascular bed in neonates in whom primary repair is high risk or if the complete repair is not possible. This may be the case with complex and multiple defects or in very small premature babies. However, these conservative strategies are questioned by some surgeons.^{134,135}

Postoperative Management. Most children undergoing elective VSD closure progress rapidly to extubation. Patients with severe cardiac failure or high PA pressures preoperatively benefit from a more cautious approach in the early postoperative period as do those with complex associated lesions. Low cardiac output or pulmonary edema may be noted in the early postoperative period as a consequence of generalized myocardial hypocontractility or due to a residual VSD (unusual with the advent of intraoperative transesophageal echocardiography). PHT is relatively rare in the current era of “early” primary repair of VSD. However, late presenting cases may have PHT, and life-threatening pulmonary hypertensive “crises” can occur in the postoperative period. Surgically placed PA catheters greatly assist in the early detection and management of such episodes.¹³⁶ Junctional ectopic tachycardia (JET)^{137,138} and complete heart block are generic risks of surgery in the vicinity of the ventricular septum. Complete heart block may be transient, but if AV synchrony has not returned by 7 to 10 days, a permanent pacing system is required.¹³⁹

Atrial Septal Defect

Anatomy. Anatomically, interatrial communications^{129,140} are of four types and can occur in isolation or in association with other CHD. An ostium secundum defect is the most common form of ASD and is centrally located in the atrial septum (fossa ovalis). An ostium primum-type defect is part of the AVSD spectrum (see below). A sinus

venosus defect occurs close to the RA-superior vena cava or RA-inferior vena cava junction and is commonly associated with partial anomalous pulmonary venous drainage. A coronary sinus defect describes a type of ASD in which the wall between the LA and coronary sinus is absent, allowing left atrial blood to reach the RA via the coronary sinus.

Pathophysiology. Left-to-right shunting of blood at the atrial level leads to RA and RV dilatation with increased pulmonary blood flow. Congestive heart failure occurs in up to 5% of children with ASD in the first year of life. Small ASDs are likely to close spontaneously in the first 2 years of life. PHT in association with ASD is relatively rare in childhood with an incidence of 13% in unoperated children <10 years of age, although patients may progress to irreversible PHT if defects are not closed.¹⁴¹ Occasionally infants or young children with primary PHT, pulmonary hypoplasia, or similar conditions present with apparently symptomatic ASD with right-to-left shunting. In these situations, the ASD is beneficial, decompressing the right heart, with symptoms being a consequence of PHT rather than simply the presence of an ASD. Atrial arrhythmias may occur in adulthood in some cases left untreated.

ASD Closure. Centrally located secundum ASD is frequently closed by placement of an ASD closure device through cardiac catheter.^{142,143} Occasionally, surgery is required in association with immediate or long-term complications of ASD device closure.¹⁴⁴ Large defects and nonsecundum defects are closed surgically with direct suture or patch and using CPB. Defects are typically closed if a child becomes symptomatic or electively between 3 and 5 years of age, as the likelihood of spontaneous closure is low after this age. There is essentially no mortality risk associated with closure of an isolated ASD and good long-term morbidity-free survival is expected.¹⁴⁵

Postprocedure Management. The vast majority of elective ASD closures progress rapidly to extubation post procedure (within hours). Specific postoperative problems seen following ASD closure include **sinoatrial node dysfunction**, which manifests as an inappropriate chronotropic response or as atrial or junctional arrhythmias. The problem is caused either by direct trauma to the sinoatrial node or interruption to its blood supply during surgery. **Postpericardiotomy syndrome** manifests as fever, malaise, lymphocytosis, nausea, vomiting, or abdominal pain in the weeks following surgery. The symptoms are caused by a sterile inflammatory process, which can cause pericardial fluid to accumulate to the point at which pericardial tamponade is manifest. A history of recent cardiac surgery with symptoms as above should raise the suspicion of the syndrome and of potential tamponade, particularly if cardiomegaly is present on chest x-ray. **PHT** is relatively rare in children after ASD repair—a previously undiagnosed ASD presenting in adulthood is more likely to be associated with PHT. **Venous obstruction** of pulmonary veins or vena cava may occur in association with repair of sinus venosus defects. **LV dysfunction** with transiently elevated LA pressure and pulmonary edema is occasionally seen after ASD closure in older patients due to chronic RV overload and decreased LV compliance.

Atrioventriculoseptal Defect

Anatomy. AVSD¹⁴⁶ results from failure of the lower part of the atrial septum to fuse with the upper part of the ventricular septum. The hallmark of all AVSDs is the presence of a common atrioventricular (AV) junction and common AV valve with 2 bridging (anterior and posterior) and 3 smaller leaflets. The common AV valve has varying degrees of competence. There are three potential components of this defect, an ostium primum ASD, a VSD, and an abnormal formation of the AV valves. The condition presents as partial AVSDs and complete AVSDs. Partial AVSDs, sometimes referred to as *primum* ASDs, present with an ASD and cleft AV valve with fused anterior and posterior bridging leaflets, creating separate right and left orifices (tricuspid and mitral valve). A complete AVSD has a VSD in addition and the bridging leaflets are not fused; thus, a common orifice is present. According to common AV valve commitment in relation to ventricles, AVSDs can be classified as balanced when equally committed to both ventricles or unbalanced if it favors one of

the ventricles, in which case hypoplasia of the opposite ventricle may occur. AVSD spectrum lesions commonly occur in children with Down syndrome.

Pathophysiology. Partial defects behave like a secundum ASD, with left-to-right shunt at the atrial level causing RA and RV volume overload. Associated incompetence of the left AV valve may lead to significant regurgitation and worsening symptoms. In complete defects, left-to-right shunting of blood at the ventricular level leads to congestive heart failure by about 2 months of age. PHT and pulmonary vascular obliterative diseases occur if repair is not undertaken by 6 to 9 months age (earlier in infants with Down syndrome).

Surgery. Partial defects are usually repaired electively between 1 and 5 years, whereas complete defects are usually repaired between 3 and 6 months to avoid severe pulmonary hypertensive complications.¹⁴⁶ Unbalanced AVSDs may undergo single ventricle palliation if associated with hypoplasia of one ventricle.

Postoperative Management. Problems seen after AVSD surgery include PHT,¹⁴⁷ although this is uncommon in the current era of early surgical repair. Residual lesions such as residual left AV valve regurgitation or residual VSD will slow postoperative recovery and require prompt diagnosis and aggressive management including reoperation if necessary. Afterload reduction with sodium nitroprusside or milrinone is useful if mild AV valve regurgitation is present following repair. If residual valve incompetence persists or increases, the operation should be revised. Elevated LA pressure following AVSD repair can occur for reasons including the presence of residual left AV valve regurgitation, left AV valve stenosis, LVOT obstruction, residual VSD, and left ventricular myocardial dysfunction. The precise cause of elevated LA pressure must be diagnosed and appropriate management instituted. Patients undergoing AVSD repair are also at risk of developing JET and complete heart block postoperatively.

Patent Ductus Arteriosus (PDA)

Anatomy. The ductus arteriosus is a vascular communication necessary in the fetal circulation between the junction of the main and left PA and the lesser curvature of the aorta (proximal descending aorta), which normally closes within 2 weeks of birth. Persistent patency occurs as an isolated defect in premature neonates and in association with other congenital heart lesions. The occurrence of PDA in premature neonates results from the low constrictor response of the immature duct to oxygen.

Pathophysiology. The key pathophysiologic abnormality in PDA, as in VSD, is left-to-right shunting leading to increased pulmonary blood flow, PHT and LV volume overload.¹⁴⁸ Neonates with this condition usually present with congestive heart failure, apneas, or respiratory problems. In term infants and older children, isolated PDA may present incidentally or with the onset of cardiac failure or problems with recurrent pulmonary infections. PHT progressing to pulmonary vascular obstructive disease can occur within the first year of life, the rate of onset of symptoms depending on the size of the duct.

Management. Indomethacin or ibuprofen are used to induce closure of PDA in premature neonates, acting through inhibition of the vasodilatory prostaglandin production, with success in about 70% cases.¹⁴⁹ Transcatheter catheter occlusion can be effective in suitable cases, with a low incidence of associated complications.¹⁵⁰ Surgical ligation or division is required in very small babies and in older children with large or tortuous ducts in whom occlusion devices cannot be safely deployed. Surgical closure is carried out via a lateral thoracotomy or as a video-assisted thoracoscopic procedure.¹⁵¹

Postoperative Management. The principal complications of conservative treatment of PDA with indomethacin or ibuprofen in preterm neonates are failure to induce closure and renal failure.¹⁴⁹ Surgical approaches may be complicated by occlusion failure and complications of thoracotomy including infection and hemorrhage. Adjacent structures including the thoracic duct, phrenic nerve, and recurrent laryngeal nerve may be damaged during surgery. Complications following transcatheter closure include residual shunt, embolization of closure device, and hemolysis.

Truncus Arteriosus

Anatomy. Truncus is caused by the failure of the common arterial trunk to divide into the aorta and PA. A single arterial vessel originates from both ventricles overriding the ventricular septum and supplying the coronary, pulmonary, and systemic circulations. Anatomic variations depend on the respective origins of the right and left PA branches from the main PA (type I), posterior (type II), or lateral (type III) aspects of the common arterial trunk or the aorta (type IV). A VSD lies immediately below a single ventriculoarterial truncal valve, which is commonly dysplastic, leading to stenosis or regurgitation. Coronary artery abnormalities are common and may lead to difficulties when conducting surgical repair. Ten to fifteen percent of the cases have associated hypoplasia, coarctation, or interruption of the aortic arch, and a small proportion of patients have stenosis or hypoplasia of the pulmonary arteries. Right aortic arch may also be present.

Aortopulmonary window is a rare lesion in which an abnormal vascular communication exists between the ascending aorta and the main PA. Like truncus arteriosus, this lesion is associated with the 22q11 chromosomal deletion^{152,153} (see later discussion).

Pathophysiology. The RV and LV are pressure and volume overloaded, particularly if truncal valve stenosis or regurgitation is present. Runoff into the pulmonary circulation due to low PVR and into the ventricles due to truncal valve regurgitation leads to a low diastolic pressure, which in the presence of high ventricular end-diastolic pressures may exacerbate myocardial ischemia. Pulmonary blood flow depends on PVR and the presence or absence of stenoses in the proximal PAs. Most commonly pulmonary overcirculation and congestive heart failure result as PVR falls in the first weeks of life. The defect is commonly associated with the 22q11 chromosomal deletion (Di George syndrome, Sphrintzen's syndrome). The important clinical manifestations associated with these include scanty or absent T cells and the consequent risk of graft versus host reactions if transfused with viable leukocytes. Irradiation of all blood products is recommended unless normal T-cell status is confirmed.

Surgery.^{154,155} The pulmonary arteries are removed from the arterial trunk, leaving a vessel that becomes the neo-aorta. A valved conduit is then placed from the RV to the pulmonary arteries, and the VSD is closed. Mortality risk is less than 10% if the truncal valve is functionally normal, no other lesions are present, and the child is of an acceptable weight. Higher mortality is seen when truncal valve replacement is required. Long-term results are encouraging although the valved conduit will require upsizing during childhood.¹⁵⁶

Postoperative Management. Specific postoperative problems associated with repair of truncus include PHT and low cardiac output. Inotropic support is required routinely, and delayed sternal closure may be employed to prevent tissue tamponade in the early postoperative period. Intensivists must be aware of the possibility of right-to-left shunting as surgeons may leave a smaller interatrial communication to decompress the RV. Failure to appreciate this mechanism may lead to an inappropriate focus on pulmonary causes of cyanosis. Right bundle branch block is common after truncus repair due to the surgical right ventriculotomy. Heart block and atrial or junctional arrhythmias are also seen. There is some evidence that children with 22q11 microdeletions have more postoperative complications than children undergoing identical surgery without deletions.

Left Heart Obstruction

Obstruction to the exit of blood from the LV can occur at subvalvular, valvular, or supra-valvular levels or more distally in the aortic arch. Babies with severe obstruction of the aortic valve or arch present in the neonatal period with either heart failure or cardiogenic shock. Aortic coarctation, aortic interruption, and critical aortic stenosis (AS) are associated with a duct-dependent systemic circulation and typically present in the first few days of life as the arterial duct closes. Less severe obstruction may be detected later as an incidental finding (murmur) or with the gradual onset of signs and symptoms including those of LV

failure. Chronic obstruction to LVOT causes LV hypertrophy, and while systolic function may initially be well preserved, reduced diastolic compliance may occur early in the clinical course. If the obstruction is unrelieved, the subendocardial region becomes ischemic and endocardial fibrosis occurs. Papillary muscle ischemia may also occur and results in acquired mitral valve regurgitation.

Valvular Aortic Stenosis

Anatomy. AS at valve level is the most common form of AS and may be associated with other left heart abnormalities (e.g., supravulvar AS, mitral valve anomalies, aortic coarctation), aortic insufficiency, and endocardial fibroelastosis. In neonatal aortic stenosis,¹⁵⁷ the LV and other left-sided structures may be hypoplastic.

Pathophysiology. Neonates with clinically apparent valvular AS present with acute left ventricular failure or shock. Systemic perfusion may be maintained by right-to-left shunting of blood across a PDA with consequent systemic desaturation and the risk of reduced systemic perfusion if the ductus closes spontaneously. The LV exhibits poor performance in both diastole and systole, and as a consequence there is high LA pressure. Pulmonary edema is a prominent clinical feature. End organ ischemic damage including renal failure and necrotizing enterocolitis are frequently seen as a consequence of poor systemic perfusion. Less severe AS typically presents later in infancy or childhood with exercise-induced syncope, chest pain, or sudden death. In these patients, concentric LV hypertrophy induced by chronic pressure overload is usually seen.

Surgery. A number of treatment options are available, with the choice of procedure dependent on age, clinical status of the child at presentation, associated anomalies, and anatomic complexity. The simplest procedure, percutaneous balloon valvotomy, is appropriate in patients with mild to moderate stenosis and favorable aortic valve anatomy.¹⁵⁸ Open aortic valve surgery is an alternative to balloon valvuloplasty and may be favored if additional procedures—for example, duct ligation—are required. If the native aortic valve cannot be salvaged or reconstructed, surgical choices include replacement of the aortic valve with a homograft or valved conduit or placement of the patient's own pulmonary valve into the aortic position with associated pulmonary homograft autograft (the Ross procedure).^{159–161} A variant of the Ross procedure, the Ross-Konno procedure, is indicated for complex LVOT obstruction in which in addition to the Ross operation, annular enlargement or aortoventriculoplasty is undertaken.¹⁶²

Postoperative Management. Most neonates presenting in heart failure or shock who undergo urgent procedures remain critically ill postoperatively and require ongoing multiorgan support.¹⁶³ If low cardiac output persists following repair, residual AS or regurgitation must be excluded. Inotropic and vasodilator support of the failing myocardium should be guided by serial hemodynamic and echocardiographic evaluations. Relief of AS in older children may be associated with systemic hypertension secondary to the unrestrained force of contraction of the hypertrophied LV. Children undergoing prosthetic valve replacement require long-term anticoagulation therapy.¹⁵⁹

Subvalvular Aortic Stenosis

Anatomy. Subvalvular AS¹⁶⁴ is seen in various forms including a fibrous diaphragm-like ring with a central orifice; a fibromuscular tunnel, frequently associated with hypoplasia of ascending aorta and LV anomalies; or simply as dynamic obstruction due to hypertrophy of the LVOT. Subvalvular AS presents in neonates in association with other lesions including malalignment-type VSD, double-outlet RV, and aortic or aortic valvular lesions or as an isolated lesion in childhood.

Pathophysiology. Similar to valvular AS, pressure overload in LV leads to hypertrophy with resultant raised pressure overload.

Surgery. The choice of surgical procedure depends on the anatomic substrate. Membranous subvalvular AS requires simple resection. The tunnel form may be suitable for resection or require a more extensive Konno or Ross-Konno-type procedure. Finally, the hypertrophic form of subvalvular AS requires a Ross-Konno operation with resection of LV myocardium.^{159,162} Some children with a small-diameter

aortic valve and endocardial fibroelastosis of the LV with poor function may not be suitable for biventricular repair and are palliated by creation of cavopulmonary circulations.

Postoperative Management. The perioperative course is usually uneventful after resection of membranous subvalvular AS although later recurrence is common. Following surgery for tunnel and hypertrophic forms of subvalvular AS, the recovery pathway is determined by the age of the child, the nature and complexity of surgery performed, and most critical of all, the size and function of the LV. Specific postoperative problems include **residual LVOT stenosis, mitral regurgitation, VSD with L-R shunt, and left bundle branch block or complete heart block** secondary to resection of left ventricular myocardium.

Supravulvar Aortic Stenosis

Anatomy. Supravulvar AS may be a localized or diffuse narrowing above the sinotubular junction. The stenosis is occasionally associated with a hypoplastic ascending aorta, and there may be compromise to coronary filling. It can occur in isolation and in association with Williams syndrome (supravulvar AS, RV outflow tract–RVOT obstruction, peripheral pulmonary stenosis, renal artery stenosis).^{165,166}

Pathophysiology. Similar to valvular AS, pressure overload in the LV leads to hypertrophy, with resultant raised pressure overload. In addition, coronary arteries fill under high pressure and may become tortuous and dysplastic.

Surgery. Patch angioplasty is performed in most cases. There is a significant risk of postprocedural coronary ischemia as coronary perfusion pressure is acutely lowered when the supraaortic obstruction is released.

Postoperative Management. The postoperative course is usually uneventful. Specific postoperative problems include **residual aortic or LVOT stenosis** leading to cardiac failure and **coronary ischemia**, which occurs if the repair has disturbed the coronary arteries or if LV hypertension and LV subendocardial ischemia persist. Care should be taken to avoid excessive systemic vasodilatation or hypotension, which might lead to coronary ischemia.

Aortic Coarctation

Anatomy. Aortic coarctation is a constriction of the thoracic aorta in the region of the left subclavian artery where the ligamentum arteriosum originates. The complexity of the lesion varies from a discrete narrowing to more extensive aortic arch hypoplasia extending back to the proximal aortic arch.¹⁶⁷ Coarctation commonly coexists with VSD¹⁶⁸ and can also be associated with other left-sided lesions including aortic and mitral valve stenosis.

Pathophysiology. In the neonatal presentation of aortic coarctation, a normal circulation is maintained until ductal tissue contracts, at which point distal aortic flow is severely reduced, leading to a clinical presentation of heart failure or shock and characteristic loss of lower limb pulses.¹⁶⁹ Prostaglandin E1 or E2 infusion should be started as soon as the diagnosis of a duct-dependent lesion is suspected in order to reopen or maintain patency of the ductus arteriosus. Following initial resuscitation, urinary output and resolution of metabolic acidosis are early indicators of successful reperfusion of the distal aorta. Early surgical repair is indicated.

Beyond the early neonatal period, aortic coarctation presents as progressive onset of cardiac failure or as an incidental finding (murmur, upper limb hypertension, absent weak femoral pulses) later in childhood. Thoracic aortic collaterals develop and may be noted as rib notching on a plain chest x-ray.

Surgery. In the neonatal period, surgical resection of the narrowed aortic segment and associated ductal tissue is followed by either direct anastomosis or repair with a subclavian flap or similar angioplasty without CPB.¹⁷⁰ If aortic arch hypoplasia is more extensive a homograft or prosthetic tube graft may be incorporated in the repair and CPB may be required.¹⁷¹ Neonatal coarctation associated with VSD can be palliated by resection of the coarctation and banding of the PA to restrict pulmonary blood flow, with delayed VSD repair, especially in the context of high PVR. Alternatively, both lesions can be corrected

in the neonatal period.¹⁶⁸ The mortality rate for repair of neonatal coarctation is low. Kanter et al. reported 91% survival in a series that included both isolated and complex coarctation.¹⁷² In older children, mortality is <1%, although paraplegia secondary to interruption of spinal cord perfusion remains a concern.

Balloon angioplasty with or without endovascular stent placement is frequently used to alleviate recurrent aortic coarctation and is increasingly being used with apparent success, to address native coarctation particularly in older patients but is not favored in symptomatic neonates.^{170,173}

Postoperative Management. Specific postoperative problems include **systemic hypertension**, which is thought to be due to multiple factors including altered baroreceptor and adrenal catecholamine and renin-angiotensin axes.^{174,175} Persistent hypertension is less common following neonatal repair, and when present it usually responds to short-term vasodilator therapy.^{174,176} Additional beta adrenergic blockade (esmolol,¹⁷⁷ propranolol, or labetalol) may be required, particularly with late presenting coarctation, but should be used with caution if ventricular function is impaired. Some children have persistent hypertension following repair¹⁷⁸ and require long-term antihypertensive therapy. **Postcoarctectomy syndrome**¹⁷⁹ occurs in older patients and is thought to be the result of restoration of higher pressure pulsatile flow to the mesenteric arterial tree and presents as abdominal distention, abdominal pain, ascites, or occasionally, enteric infarction. The condition is best managed by avoiding enteral feeding for 24 hours following repair and aggressive treatment of systemic hypertension. The necessity of aortic clamping during surgical repair interrupts distal aortic flow and may result in spinal cord ischemia (rare in neonates, 0.4% incidence in older patients) or renal ischemia. Intensivists must seek positive confirmation of lower limb movement and adequate renal function in the early postoperative period. In neonates low cardiac output may persist due to preexisting ventricular dysfunction, although residual coarctation should be excluded. Structures near the aortic arch prone to surgical injury include the thoracic duct, recurrent laryngeal nerve, and phrenic nerve, leading to postoperative chylothorax, stridor, or hemidiaphragm paralysis.

Interrupted Aortic Arch (IAA)

Anatomy. In this condition, the aortic arch is either atretic or interrupted, creating either complete disruption or luminal obstruction (without external interruption). It is classified according to the location of the interruption along the aortic arch, which may be distal to the left subclavian artery (type A), between the left common carotid and left subclavian arteries (type B), or between the brachiocephalic trunk and left common carotid arteries (type C). A PDA is necessary to maintain perfusion of the distal aortic arch, closure of which leads to emergent presentation. A VSD and obstruction of the LVOT commonly coexist. The more common form of interrupted aortic arch, type B, is associated with the 22q11 chromosomal deletion^{152,153} (see above).

Pathophysiology. Interrupted aortic arch can be regarded as a severe form of aortic coarctation, with duct-dependent distal aortic perfusion, and requires similar initial management.¹⁶⁹

Surgery. Surgical reconstruction of the aortic arch and closure of the associated VSD are usually undertaken under CPB in the neonatal period.

Specific postoperative problems seen after repair of interrupted aortic arch include PHT, residual aortic arch obstruction, and residual VSD. There is a risk of transfusion-associated graft-versus-host disease and hypocalcemia in children with type B interrupted aortic arch associated with 22q11 deletion and Di George phenotype.¹⁸⁰

Cyanotic Lesions

Tetralogy of Fallot (TOF)

Anatomy. Tetralogy of Fallot¹⁸¹ was initially described in the 19th century as an association of four anatomic findings: VSD, subpulmonary stenosis, aortic override of the ventricular septum, and right ventricular hypertrophy. The four lesions are actually the result of just one central

problem, anterior and superior malalignment of the infundibular septum with respect to the muscular septum, which creates an obstruction in the RVOT and leads to the four features seen. Coronary artery abnormalities may also be present, and a right-sided aortic arch is seen in approximately 20% of cases. Children presenting with TOF should be investigated for a 22q11 microdeletion (see previous discussion).

Pathophysiology. Preoperative physiology depends mainly on the degree of RVOT obstruction. Patients with minimal RVOT obstruction have unrestricted pulmonary blood flow with left-to-right shunt through the VSD. Conversely patients with severe obstruction will be cyanosed with saturations in the 70% to 80% range preoperatively as a result of right-to-left shunting across the VSD. RVOT obstruction is often dynamic and may cause profound cyanosis (hypercyanotic spells), which requires treatment aimed at alleviating the dynamic RVOT obstruction and maintaining right heart output. Treatment of such episodes requires oxygen, sedation, and volume expansion. The knee-chest or over-shoulder positions compress the liver and increase RV filling. If such maneuvers fail, beta blockade (propranolol 0.1 mg/kg) or vasoconstriction (e.g., phenylephrine 5–20 µg/kg IV, max 500 µg per dose) may be required or, as a last resort, preoperative ECMO support.

Surgery. The timing and type of surgical intervention in TOF is controversial.^{182,183} Complete repair is usually undertaken in the first year of life with VSD closure, RVOT obstruction relief, and pulmonary valvotomy. However, some centers adopt a two-stage approach with initial placement of a modified systemic-to-pulmonary arterial (Blalock-Taussig) shunt to secure pulmonary blood flow in cyanotic neonates with complete repair being undertaken after a few months. Surgical repair of the RVOT obstruction can be complex if major coronary abnormalities are present, especially with the anterior descending branch originating from the right coronary artery and running over the RVOT.

Specific Postoperative Problems. Residual VSD is poorly tolerated after TOF repair and requires early surgical closure. Moderate degrees of residual RVOT obstruction may be well tolerated in the early postoperative period, but severe residual obstruction demands early reinvestigation and reoperation with placement of a larger RVOT patch or valved RV-PA conduit. All patients with a right ventricular incision develop right bundle branch block. JET is poorly tolerated after Fallot repair.¹⁸⁴ Low cardiac output due to RV dysfunction is relatively common and should be suspected if the child is hypotensive and tachycardic and has a raised CVP and hepatomegaly. The problem is predominantly one of poor RV compliance, often referred to as *RV restriction*¹⁸⁵ and typically resolves in 3 to 5 days. Until recovery occurs, the heart should be supported by optimizing RV filling and ensuring AV synchrony. Negative pressure ventilation has been shown to improve cardiac output where RV restriction exists.^{17,186}

Pulmonary Atresia with Intact Ventricular Septum¹⁸⁷

Anatomy. In this condition, there is complete obstruction to the RVOT, along with a variable degree of hypoplasia of the RV and tricuspid valve, which may also be incompetent. Pulmonary blood flow occurs via a PDA. Coronary artery sinusoids or fistulae are often found in severe pulmonary atresia with intact ventricular septum and a small RV. Ten percent of cases will have a right ventricular-dependent coronary circulation, where coronary sinusoids/fistulae are associated with proximal stenosis, and perfusion of areas of myocardium is dependent on flow via the RV. In some patients, the pulmonary arterial supply is abnormal, with segments of the lungs being supplied solely or partially ("dual supply") from systemic collateral vessels termed *major aortopulmonary collateral arteries* (MAPCA).¹⁸⁸ Children presenting with this condition should be investigated for a 22q11 micro-deletion (see previous discussion).

Pathophysiology. Preoperatively, there is complete mixing of systemic and pulmonary venous return in a duct-dependent circulation. The RV may be very hypertensive since there is no path for egress of blood. Some blood may pass via coronary sinusoids, if present, or back through a regurgitant tricuspid valve.

Surgery. The goal of treatment is to provide a secure source of pulmonary blood flow balanced to systemic flow and to permit the RV to develop to its maximal potential, always aiming for a two-ventricle repair where possible.^{188,189} Interventional procedures are needed in all cases in the fetal¹⁹⁰ or neonatal period^{191,192} because of duct dependency. Subsequent strategies are chosen according to individual anatomic findings.

In severe forms of the condition (severe RV hypoplasia + coronary fistulae) a two-ventricle repair will never be possible and a palliative approach is adopted. Initial palliation secures pulmonary blood flow with systemic-to-pulmonary artery shunts (30%-40% PA/IVS), with the ultimate aim being a single-ventricle Fontan circulation (see later discussion). In contrast, babies with a normal-sized RV may be suitable for RVOT reconstruction in the neonatal period, therefore avoiding shunting and ending up with early anatomic correction (10% of cases). An intermediate group of patients, the majority of cases of PA/IVS, need initial palliation with decompression of the RV by radiofrequency perforation of the atretic pulmonary valve or outflow tract patch, and often require a systemic-to-pulmonary artery shunt. They progress to either a single, "one-and-a-half"¹⁹³ or biventricular repair depending on subsequent development of the RV and PA. Fetal cardiac valvuloplasty may have a role in the management of this condition in the future.¹⁹⁰

Specific Postoperative Problems. These include low cardiac output due to excessive runoff through the shunt, myocardial ischemia due to decompressed coronary fistulae, or low systemic diastolic pressure due to excessive shunt runoff.¹⁹⁴

Transposition of the Great Arteries (TGA)

Anatomy. In TGA,^{195,196} which accounts for 5%-7% of all CHD, the great vessels are transposed so that the aorta arises from the anatomic RV and the PA from the LV, so-called ventriculoarterial discordance. It is also called complete TGA or D-TGA, which refers to the aorta being positioned right and anteriorly to the PA. The condition occurs with a VSD in approximately 40% of cases. Other commonly associated lesions include coarctation (10%), LVOT obstruction (5%), and coronary abnormalities (33%). Congenitally corrected TGA is a different and rare pathology in which both atrioventricular and ventriculoarterial discordances are present, with the aorta positioned left to the PA (also called L-TGA).

Pathophysiology. The predominant finding in TGA is cyanosis due to parallel rather than serial function of the pulmonary and systemic circulations, with the greatest proportion of the output of a ventricle being recirculated to that ventricle. Survival is therefore dependent on the presence of mixing between the two circulations (Fig. 83-2). The presence of either a PDA or VSD alone or in combination without an atrial communication does not ensure adequate mixing of the two circulations. If the diagnosis is suspected in a neonate, an infusion of prostaglandin E1 or E2 should be established to maintain ductal patency, and following echocardiographic confirmation of the diagnosis, a balloon atrial septostomy is sometimes necessary to enlarge the foramen ovale and secure mixing at the atrial level, particularly if the foramen ovale is restrictive, leading to high pulmonary venous pressures. Saturations typically increase from very low levels (<50%) to 65%-85% following these interventions, and it is then usually possible to discontinue the prostaglandin infusion.

Surgery. The preferred surgical option in the current era is the arterial switch (Jatene) operation,¹⁹⁵⁻¹⁹⁸ although long-term results following Senning operations also appear to be acceptable.¹⁹⁹ The switch operation is usually performed within the first 2 weeks of life, beyond which the LV (functioning as a low-pressure subpulmonary or right ventricle since birth) is less able to cope with systemic pressures.²⁰⁰ Babies with a large VSD have equal ventricular pressures, and repair can be delayed a little longer, although in practice most surgeons repair TGA with VSD within the first month of life. The operation consists of transection of the aorta and PA with reconstruction of the vessels in their anatomic position, which necessitates transfer of the coronary arteries from the aorta (neo-PA) to the PA (neo-aorta).

FIGURE 83-2 ■ **A**, Normal series circulatory arrangement. **B**, Parallel circulation of transposition of the great vessels.

Specific Postoperative Problems After the Arterial Switch Operation. Left ventricular dysfunction is common in babies during the first 12 hours following the arterial switch operation.²⁷ It may be a sign of coronary insufficiency²⁰¹ or of acute dysfunction secondary to an unprepared/involved LV, or simply nonspecific post-CPB low cardiac output. In the absence of ECG or echocardiographic evidence of regional coronary ischemia, low cardiac output is managed conservatively. The postoperative LV of neonates is poorly compliant. Therefore rapid volume infusion should be avoided as LV distention and ischemia may result. Preload should be augmented gradually, titrating volume infused against measured left atrial pressure.

Alternative Surgical Techniques. Atrial switch operations (the Senning and Mustard procedures) are alternatives to the arterial switch operation and may be chosen in infants presenting beyond the early neonatal period in whom a one-stage arterial switch is not possible due to deconditioning of the LV. In atrial switch operations, blood is diverted by an atrial baffle to establish a series circulation leaving the RV as the systemic ventricle. It is believed that the burden of late complications such as RV failure is greater after atrial switch procedures. An alternative strategy for late-presenting transposition is a two-stage repair with initial banding of the PA to condition the LV with switch once the ventricle is conditioned.²⁰²

Postoperative Care. Atrial switch procedures are usually performed outside the neonatal age group and, compared to arterial switch patients, have a relatively uneventful postoperative course.

Atrial volumes and compliance are reduced by the procedure such that postoperatively left and right atrial pressures must be maintained at higher than normal levels to maintain ventricular filling. Slow heart rates and arrhythmias are poorly tolerated.

Complex Single-Ventricle Circulations

Some defects are such that they can never be corrected to provide two functioning ventricles.^{203,204} These complex arrangements include any heart in which one ventricle is hypoplastic such that it would be incapable of supporting either the pulmonary or systemic circulation independently. Examples of such situations include tricuspid atresia or double-inlet LV. In these examples the RV has failed to develop adequately and is connected to a dominant LV via a VSD. Flow to the circulation supplied by the rudimentary ventricle originates from the dominant chamber and is dependent on an adequate VSD. Children with this type of anatomy will always have two ventricles, even if one is hypoplastic, but physiologically they behave as if the heart consists of only a single ventricle.

Complex single-ventricle hearts can be palliated with a series of interventions leading to creation of a Fontan circulation in which the systemic and pulmonary circulations are completely separated.²⁰⁵ Initially adequate intracardiac communications are established to ensure both systemic and pulmonary venous return have unobstructed access to the dominant ventricle that supplies both systemic and pulmonary blood flow. If necessary, pulmonary flow is augmented by the use of a systemic-to-PA shunt or RV-to-PA conduit. Systemic and pulmonary blood flow is assured at the expense of mixing of pulmonary and systemic venous returns, with consequent cyanosis and volume loading of the single ventricle.

Subsequently, if hemodynamic conditions are favorable, the Fontan circulation is established, usually in two-staged procedures. Initially a bidirectional cavopulmonary (Glenn operation) or a “hemi-Fontan” anastomosis is created in which the SVC is connected to the proximal right PA. This has the benefit of reducing the volume load placed on the systemic ventricle by previously placed systemic-pulmonary shunt. Finally, venous return from the IVC is also directed to the pulmonary circulation. This is achieved by forming a lateral tunnel²⁰⁶ or the use of a synthetic extracardiac conduit²⁰⁷ to channel blood from the IVC to the inferior aspect of the right PA, completing the total cavopulmonary connection or Fontan circulation.

In the Fontan circulation, there is no “subpulmonary” ventricle, all ventricular tissue having been incorporated in the single ventricle that receives pulmonary venous return and ejects into the systemic circulation. This establishes a form of series circulation and results in normal systemic oxygenation and equality of pulmonary and systemic blood flow. Pulmonary blood flow in the Fontan circulation is driven by the transpulmonary hydrostatic gradient and is only viable if PVR and systemic ventricular end-diastolic pressures (pulmonary venous pressures) are low. Good systemic ventricular function and low PVR are crucial determinants of operability. Patients with Fontan circulation tolerate factors that impede systemic venous return very poorly, such as dehydration, pneumothorax, pericardial effusion, positive pressure ventilation¹²¹, raised PVR, or compromised ventricular or respiratory²⁰⁸ function. Perioperative use of ACE inhibitors²⁰⁹ has been shown to reduce the severity and duration of pleural drainage,²¹⁰ a common problem caused by high postoperative systemic venous pressures. A communication, or fenestration, between the systemic venous pathway and pulmonary venous atrium may be created in patients thought to be at higher risk of complications such as effusions or perioperative low cardiac output as a result of relatively high PVR.

Long-term follow-up studies have demonstrated that systemic ventricular function remains abnormal after Fontan procedures.²¹¹ Ultimately, the Fontan circulation may fail and cardiac transplantation be considered.

Hypoplastic left heart syndrome (HLHS) is a term encompassing a range of hypoplastic abnormalities of the left-sided cardiac structures and connections including the ascending aorta.²¹² The condition is

usually palliated in three stages, although some authorities prefer to offer cardiac transplantation without prior palliative surgery.²¹³ The first-stage procedure secures systemic and pulmonary blood flow with either a Norwood procedure or similar or a hybrid procedure.^{214,215} The Norwood approach consists of reconstruction of the aortic arch and the establishment of pulmonary blood flow via a central systemic-to-pulmonary artery shunt. Some advocate replacing the systemic-to-pulmonary artery shunt of the classical Norwood with an RV-to-PA conduit, which may be easier to manage postoperatively as there is potentially less diastolic runoff, with less risk of coronary ischemia, than occurs across the central shunt of the classical Norwood operation.²¹² In a large randomized trial comparing modified Blalock-Taussig shunt to RV-PA conduit shunt in infants with hypoplastic left heart syndrome or related single right ventricle anomalies who underwent Norwood procedure, those in the RV-to-PA conduit group had higher transplantation-free survival at 12 months.²¹⁶ However, patients on the RV-to-PA conduit group experienced more complications and unexpected cardiovascular interventions.

Balancing the pulmonary and systemic circulations in the immediate postoperative period can be challenging. Interventions such as sudden hyperventilation or increases in oxygen concentration that lower PVR should be avoided. Strategies to manage the postoperative Norwood patient include the use of long-acting vasodilators such as phenoxybenzamine^{32,33} and close monitoring of cerebral oxygenation, venous oxygen saturation, and plasma lactate. ACE inhibitors are subsequently introduced, and very close interstage monitoring may be undertaken in an attempt to minimize interstage morbidity and mortality.

Following the first-stage procedure, a bidirectional cavopulmonary anastomosis is undertaken typically between 2 and 6 months of age, and finally a completion to a Fontan circulation follows at 18 to 24 months of age. Fetal diagnosis facilitates early and appropriate management and may contribute to improved outcomes in HLHS,²¹⁷ although there is known to be significant risk of poor neurodevelopmental status in survivors of neonatal HLHS interventions.²¹⁸

Pulmonary Vein Abnormalities

Anomalous Pulmonary Venous Connection

Anatomy. Pulmonary veins drain anomalously into a systemic venous structure and subsequently to the RA rather than directly into the LA. The condition may affect all pulmonary veins (total anomalous pulmonary venous connection, TAPVC) or fewer, typically one vein (partial anomalous pulmonary venous connection). In *supracardiac* TAPVC (45% of cases) the pulmonary veins drain via a vertical vein to the innominate vein or connect directly into the SVC. In *intracardiac* TAPVC (25% of cases) the venous confluence drains via the coronary sinus into the RA, and in *infracardiac* TAPVC (25% of cases), the veins drain into the IVC or portal veins. Mixed forms also exist (5% cases).²¹⁹ TAPVC is associated with an obligate ASD to allow mixing of systemic and pulmonary venous return to access the LV and systemic circulation.

Pathophysiology. In the case of TAPVC, two patterns emerge depending on presence of obstruction to the pulmonary venous return. Obstruction of the pulmonary venous pathway is common (especially in the infracardiac type) and causes pulmonary venous hypertension and edema, reflex PA vasoconstriction, and subsequent right heart failure. If obstruction is not present, the main pathophysiologic effects result from complete mixing of systemic and pulmonary venous blood in the right heart with RV volume overload and failure. Partial anomalous venous connection has similar pathophysiology to that of ASD, with RA and RV dilatation and pulmonary overflow.

Surgery. The pulmonary veins are anastomosed or baffled into the LA. In the current era, the expected operative mortality is less than 5%, although higher risks are reported in complex cases with associated lesions.²²⁰ Babies presenting with life-threatening obstruction must undergo emergency surgery or a short period of preoperative stabilization with ECMO followed by surgery.

Specific Postoperative Problems. PHT, which may, on occasion, be severe or even life threatening, is common in infants following surgery for obstructed anomalous pulmonary veins.¹⁴⁷ If high PA pressure occurs postoperatively, it is essential to rule out residual pulmonary vein obstruction. Late restenosis is seen in up to 10% cases and carries a poor prognosis, often related to a progressive fibrotic process occluding the lumen of the pulmonary veins.²²¹

Other Lesions

Vascular Rings and Slings

Vascular rings and slings²²² result from abnormal branching or positioning of the great vessels, which in turn, result in encirclement or compression of the trachea and/or the esophagus. They are seen in isolation or in association with intracardiac defects.

Anatomy. Three common types occur either in isolation or in association with other cardiac lesions including right aortic arch, tetralogy of Fallot, and AVSDs.

- Double aortic arch

This results from failure of the embryonic regression of one of the arches. The right arch, which is commonly dominant and usually larger, passes posterior to the esophagus and trachea to connect to the left-sided descending thoracic aorta, forming a vascular ring. The left arch is commonly smaller and may exhibit varying degrees of hypoplasia, coarctation, or true atresia. The carotid and subclavian arteries originate from both arches. Sometimes a PDA or ligamentum arteriosum forms a true ring around the trachea.

- Right aortic arch with aberrant left subclavian artery

In this condition, the left subclavian has its origin from the ascending aorta and courses to the left behind the esophagus with the vascular ring completed by the ligamentum arteriosum.

- PA sling

The left PA arises from the right PA and passes to the left by passing behind the trachea. The trachea is squeezed between the aorta and the left PA, and a true ring may be formed by a PDA or ligamentum arteriosum.

Pathophysiology. Vascular rings have the potential to compress both trachea and esophagus. PA slings usually cause chronic tracheal compression, which eventually results in destruction of the tracheal skeleton with resultant tracheal stenosis in 50% of cases.

Surgery.^{223,224} Vascular rings are usually approached via a lateral thoracotomy (usually left). The left arch or ligamentum is divided to release the ring, and the descending aorta is dissected away from the esophagus. To correct PA sling, the anomalous left PA is transected and rerouted anteriorly and reanastomosed to the central PA.

Postoperative Care. This is usually uneventful. Extubation at the end of anesthesia or early in the ICU course is expected. **Tracheomalacia** may persist or present postoperatively, especially after PA sling surgery, and may require long periods of respiratory support postoperatively via a tracheostomy.

Anomalous Left Coronary Artery from the Pulmonary Artery

Anatomy. ALCAPA usually occurs as an isolated lesion in which the left coronary artery arises from the PA rather than the aorta.

Pathophysiology. Symptoms develop gradually as PVR falls during early infancy. There is progressive onset of myocardial ischemia as left coronary flow falls in parallel with the fall in PA pressure. The myocardium is initially well perfused by desaturated PA blood, but as coronary flow falls, severe left ventricular ischemia and dysfunction occur.

Surgery. Surgical intervention is necessary to reconnect the left coronary with the aorta, and this can be achieved either by creating a tunnel from the left coronary orifice to the aorta²²⁵ (the Takeuchi operation) or by directly reimplanting the coronary artery.²²⁶

Postoperative Care. The principal perioperative problem in infants with symptomatic ALCAPA is management of low cardiac output. Beta adrenergic agonists, PDE III inhibitors such as milrinone,²⁶ and occasionally mechanical circulatory support may be required.

SPECIFIC ISSUES FOR INTENSIVISTS

Surgical Control of Pulmonary Blood Flow-PA Banding

PA banding is a surgical procedure in which a constriction is created in the main PA with the physical effect of limiting pulmonary blood flow. The aim is to protect the lungs from excessive blood flow, thus maintaining a balance between the systemic and pulmonary circulations, and to prevent the onset of PHT in some complex anomalies unsuitable for early anatomic repair.²²⁷ PA banding is primarily a palliative procedure and usually a stepping stone to a later definitive or more complex repair. It is performed without CPB through either a left thoracotomy or median sternotomy.

Physiology

The reduction of pulmonary blood flow by a PA band limits volume loading of the systemic or single ventricle. Arterial saturations may be 75% to 85% following effective banding, with pressure gradient typically in the range of 40 mm Hg to 60 mm Hg in a neonate. However, arterial saturations above 90% may be reached where complete mixing occurs.

Specific Management Issues

Very low oxygen postoperative saturations ($\text{SaO}_2 < 70\%$) may indicate restricted pulmonary blood flow by tight banding, although low cardiac output with consequent low mixed venous saturations may also be a factor. Urgent echo evaluation of the band gradient²²⁸ and exclusion of other causes of hypoxemia should be undertaken. If hypoxemia persists, and particularly if significant metabolic acidosis develops, urgent relief or removal of the band may be indicated.

High oxygen saturations in excess of 90% should alert the possibility of PA band being too loose and ineffective in controlling pulmonary blood flow. Signs of congestive cardiac failure may be noted and require medical treatment (diuretics) or further surgical interventions (rebanding or lesion correction).

Delayed Sternal Closure

Complex cardiac surgery involving CPB can result in edema of the myocardium and other mediastinal tissues. Sternal closure at the end of the surgical procedure may cause cardiac compression (tissue tamponade), which decreases ventricular compliance and leads to reduced cardiac output and elevated pulmonary venous pressures.^{229,230}

In such a situation, it is not uncommon for the child to return to the ICU with an open chest and to defer the sternal closure in the unit once the hemodynamic situation has improved. Transient deteriorations at delayed closure are usually self-limiting and tolerated; however, hypotension, oliguria, rising plasma lactate, or falling venous saturations suggest suboptimal cardiac output reserve and closure will not be tolerated.²³¹ Although temporal delay in sternal closure may be essential in some cases, it has to be balanced with the possibility of associated increased risk of surgical site infection.²³²

Infective Endocarditis

Children with CHD are at higher risk of developing infective endocarditis, especially those with cyanotic diseases.²³³ While prophylactic antibiotic treatment prior to noncardiac procedures is no longer recommended in children and young people with native heart valve disease,²³⁴ prophylaxis is still recommended prior to dental procedures for patients with a previous episode of infective endocarditis, prosthetic valves, cardiac transplant recipients who develop valve dysfunction, and patients with certain CHD, such as cyanotic CHD not fully repaired (including shunts and conduits), any CHD fully repaired using surgical or catheter-placed prosthetic material or device for 6 months after procedure, and any CHD fully repaired that

present residual defect adjacent to or at the site of prosthetic patch or device. Intensivists should aim to minimize the risk of catheter-related blood-stream infection complications by employing best practice guidelines with care bundles to include surveillance of central venous catheters.²³⁵

Thrombosis and Prophylaxis

Children with CHD are at risk of thrombosis, which may contribute to higher morbidity and mortality, especially in those with cyanotic CHD and shunt-dependent circulation. Recommendations for thrombosis prevention and treatment in children have been recently reviewed, with special consideration given to CHD and surgical procedures such as systemic-to-pulmonary shunts, cavopulmonary anastomosis, and valve replacement.^{236,237}

Of additional importance to intensivists is central venous catheter—associated thrombosis in children with CHD as it may adversely affect surgical plan and outcome ultimately. Central venous catheters should be avoided or removed as soon as no longer needed in these patients. Low-dose heparin may be considered for patients who present with additional thrombosis risk factors and those planned for total cavopulmonary anastomosis.²³⁷ Prompt catheter removal and systemic anticoagulation should be considered for documented catheter-associated thrombosis after weighing the risk of embolization.

Chylothorax

The incidence of chylothorax following cardiac surgery in children is around 3%, with higher figures according to procedure's complexity and in cavopulmonary anastomosis.^{238,239} Morbidities associated with chylothorax include respiratory failure, venous thrombosis, immunosuppression, and malnutrition. Patients receiving normal fat containing feeds will present with opaque, milky pleural drainage. Diagnosis is confirmed by fluid analysis, which shows triglyceride content >1.1 mmol/L (if on fat containing feed) and white cell count >1000 cells per mm^3 with lymphocytes $>80\%$.²⁴⁰ Initial management is based on feeding strategies that include medium-chain triglycerides—only enteral feed, low-fat modular diet with intravenous lipid administration, or total parenteral nutrition. Surgical drainage is frequently required for respiratory distress or failure to wean from ventilatory support. Further management with octreotide infusion may be an option in selected cases, and surgical treatment may be required if medical management is unsuccessful.^{238,241} Depletion of plasma proteins including clotting factors and immunoglobulins may occur if high losses are not controlled and may warrant replacement.

Sepsis and Infection

Common hospital-acquired infections after cardiac surgery include superficial surgical site infection, catheter-related bloodstream infection, and ventilator-associated pneumonia. Rare but important are deep soft tissue infections such as cellulitis, sternal osteomyelitis, and mediastinitis. Care bundles in association with aseptic technique practices and antibiotic prophylaxis can reduce the incidence of procedure-related and hospital-acquired infection. For surgery and interventions, antibiotic prophylaxis is recommended prior to skin incision. Choice of antibiotic should cover known common gram-positive and gram-negative organisms, according to local guidelines

and known patterns of bacterial resistance. Short-duration therapy—that is, less than 48 hours—should be aimed for surgical prophylaxis as prolonged administration does not seem to reduce further surgical site infection and is associated with acquired antimicrobial resistance.²⁴² Should infection or sepsis be suspected or confirmed, antimicrobial therapy has to be based on local epidemiology and ideally with microbiologist consultation. Optimal therapy includes adequate dosing with close monitoring of serum levels where available and treatment review guided by microbiology and antibiogram results along with clinical progress.

Rhythm Disturbance After Cardiac Surgery

Children undergoing cardiac surgery may present with rhythm disturbance perioperatively, a situation that can contribute to increased morbidity and require urgent treatment.²⁴³ Dysrhythmias can develop following direct surgical damage or stimulation of the cardiac conduction system, or secondary to systemic conditions such as electrolyte imbalance, high core temperature, hypoxia, circulating catecholamine, or low cardiac output state. Although a variety of arrhythmias can occur after cardiac surgery, they are often related to the proximity of surgical site to cardiac conduction system (see specific lesions). Treatment of associated conditions such as electrolyte abnormalities and hemodynamic instability, antiarrhythmic drugs, and temporary pacing may be needed. Complete heart block may be transient, but if AV synchrony has not returned by 7 to 10 days after surgery, a permanent pacing system is required.¹³⁹

Necrotizing Enterocolitis

Neonates with CHD are at risk of developing necrotizing enterocolitis, especially those presenting with left heart obstruction and single-ventricle physiology. Additional risk factors are prematurity, hemodynamic instability, infection, and enteral nutrition, notably with formula.²⁴⁴ Neonates with NEC classically present a triad of abdominal distention, gastrointestinal bleeding, and pneumatosis intestinalis. In severe cases intestinal perforation and/or septic shock is seen. Initial management includes nil per os and gastric decompression, hemodynamic stabilization, and triple antibiotics with close monitoring and case review at least 6 to 12 hourly. Further surgical management may be required if advanced injury or perforation exists.

KEY POINTS

1. Appropriate intensive care management of the congenital heart patient must be based on a sound understanding of the anatomy and pathophysiology of the child's circulation.
2. Issues relating to the management of intracardiac shunts, cyanosis, and the management of the pulmonary circulation and right ventricle are of great importance in managing children with CHD.
3. Specialist advice should be sought early if children with known or suspected heart disease are admitted to nonspecialist pediatric or adult facilities.

ETIOLOGY AND CLASSIFICATION OF PERICARDIAL DISEASE

The spectrum of pericardial diseases consists of congenital defects, pericarditis (dry, effusive, effusive-constrictive, or constrictive), neoplasms, and cysts. The etiologic classification comprises infectious pericarditis, pericarditis in systemic autoimmune diseases, type 2 (auto) immune process, postmyocardial infarction syndrome, and autoreactive (chronic) pericarditis.¹⁻³

PERICARDIAL SYNDROMES

Congenital Defects of the Pericardium

Congenital defects of the pericardium are found in 1 in 10,000 autopsies. Pericardial absence can be partial left (70%), partial right (17%), or total bilateral (rare). Additional congenital abnormalities occur in approximately 30% of patients.⁴ Most patients with total pericardial absence are asymptomatic. Homolateral cardiac displacement and augmented heart mobility impose an increased risk for traumatic aortic dissection.⁵ Partial left-side defects can be complicated by herniation and strangulation of the heart through the defect (causing chest pain, shortness of breath, syncope, or sudden death). Surgical pericardioplasty (Dacron, Gore-Tex, or bovine pericardium) is indicated for imminent strangulation.⁶

Acute Pericarditis

Acute pericarditis is dry, fibrinous, or effusive, independent of its etiology. The major symptoms are retrosternal or left precordial chest pain (which radiates to the trapezius ridge, can be pleuritic or simulate ischemia, and varies with posture) and shortness of breath. A prodrome of fever, malaise, and myalgia is common, but elderly patients may not be febrile. A pericardial friction rub can be transient and monophasic, biphasic, or triphasic. A pleural effusion may be present. The heart rate is usually rapid and regular. Echocardiography is essential to detect effusion and concomitant heart or paracardial disease (Table 84-1).⁷⁻¹⁹

Hospitalization and symptomatic treatment are warranted. Nonsteroidal antiinflammatory drugs (NSAIDs) are the mainstay. Indomethacin should be avoided in elderly patients owing to its effect on reducing flow in the coronaries. Ibuprofen (300 to 800 mg tid) is preferred for its rare side effects, favorable impact on coronary blood flow, and large dose range.⁷ Colchicine 0.5 mg at least twice daily for 3 months added to aspirin or another NSAID reduced the recurrence rate impressively in the COPE trial,²⁰ even at the first episode of pericarditis or even as monotherapy in “idiopathic” effusions. Colchicine is well tolerated, with fewer side effects than NSAIDs. Systemic corticosteroids should be restricted to connective tissue diseases and autoreactive or uremic pericarditis. Intrapericardial steroid application, as long-acting crystalloid triamcinolone, is effective for autoreactive effusions and avoids systemic side effects.²

Chronic Pericarditis

Chronic (>3 months) pericarditis includes effusive (inflammatory or hydropericardium in heart failure), adhesive, and constrictive forms.⁷

Symptoms (chest pain, palpitations, and fatigue) are usually mild and related to the degree of cardiac compression and pericardial inflammation. The detection of curable causes (e.g., tuberculosis, toxoplasmosis, myxedema, or viral, autoimmune, and systemic diseases) allows successful specific therapy. Symptomatic treatment and pericardiocentesis should be applied, if indicated. For recurrences, the etiology should be investigated intensely, and if no specific therapy is effective, balloon pericardiotomy or pericardiectomy may be considered.^{21,22}

Recurrent Pericarditis

The term *recurrent pericarditis* encompasses (1) the intermittent type (symptom-free intervals without therapy) and (2) the incessant type (discontinuation of antiinflammatory therapy precipitates a relapse). Massive pericardial effusion, overt tamponade, or constriction is rare. Symptomatic management relies on exercise restriction and regimens used for acute pericarditis. Colchicine may be effective when NSAIDs and corticosteroids fail to prevent relapses.^{20,23-25} It should be considered the first-choice treatment for recurrent pericarditis according to the CORE trial.²³ Corticosteroids should be used only in patients with a poor general condition or in frequent crises.⁷ A common mistake could be to use a dose too low to be effective or to taper the dose too rapidly. The recommended regimen is prednisone 1 to 1.5 mg/kg for at least 1 month. If patients do not respond adequately, azathioprine (75 to 100 mg/day) or cyclophosphamide can be added.²⁶

Corticosteroids should be tapered over a 3-month period. Toward the end of the taper, introduce antiinflammatory treatment with colchicine (0.5 mg bid or tid) or an NSAID. Renewed treatment should continue for 3 to 6 months. Recently, it has been demonstrated in “idiopathic” pericarditis that previous corticosteroid treatment was a risk factor for recurrence or chronicity. Therefore, corticosteroids should be administered after the definite exclusion of viral or bacterial infection of the pericardium. Pericardiectomy is indicated only for frequent and highly symptomatic recurrences resistant to medical treatment.²⁷

Pericardial Effusion and Cardiac Tamponade

Pericardial effusion may appear as transudate (hydropericardium), exudate, pyopericardium, or hemopericardium. Large effusions are common with neoplastic, tuberculous, cholesterol, and uremic pericarditis, as well as with myxedema and parasitoses.²⁸ Loculated effusions are more common when scarring has supervened (e.g., postsurgical, posttraumatic, or purulent pericarditis). Effusions that develop slowly can be remarkably asymptomatic, whereas rapidly accumulating smaller effusions can present as tamponade. Cardiac tamponade is the decompensated phase of cardiac compression caused by effusion accumulation, leading to increased intrapericardial pressure. Heart sounds are distant. Orthopnea, cough, and dysphagia, occasionally with episodes of unconsciousness, can be observed. Insidiously developing tamponade may present as signs of its complications (renal failure, abdominal plethora, shock liver, worsening of glaucoma,²⁹ and mesenteric ischemia). Tamponade without two or more inflammatory signs (typical pain, pericardial friction rub, fever, or diffuse ST segment elevation) is usually associated with a malignant effusion (likelihood ratio, 2.9).³⁰

TABLE 84-1

Diagnostic Pathway and Sequence of Performance in Acute Pericarditis

| DIAGNOSTIC MEASURE | CHARACTERISTIC FINDINGS |
|--------------------|--|
| OBLIGATORY | |
| Auscultation | Pericardial rub (monophasic, biphasic, or triphasic) |
| ECG* | <i>Stage I:</i> anterior and inferior concave ST segment elevation. PR segment deviations opposite to P wave polarity <i>Early stage II:</i> all ST junctions return to the baseline. PR segments deviated <i>Late stage II:</i> T waves progressively flatten and invert <i>Stage III:</i> generalized T-wave inversions in most or all leads <i>Stage IV:</i> ECG returns to prepericarditis state |
| Echocardiography | Effusion types B to D (Horowitz) Signs of tamponade |
| Blood analyses | Erythrocyte sedimentation rate, C-reactive protein, lactate dehydrogenase, leukocytes (inflammation markers) Troponin I, [†] CK-MB (markers of myocardial involvement) |
| Chest radiograph | Ranging from normal to “water bottle” shape of the heart shadow Performed primarily to reveal pulmonary or mediastinal pathology |

MANDATORY IN TAMPONADE, OPTIONAL IN LARGE/RECURRENT EFFUSIONS OR IF PREVIOUS TESTS INCONCLUSIVE IN SMALL EFFUSIONS

| | |
|-----------------------------|--|
| Pericardiocentesis/drainage | Polymerase chain reaction and histochemistry for etiopathogenetic classification of infection or neoplasia |
|-----------------------------|--|

OPTIONAL OR IF PREVIOUS TESTS INCONCLUSIVE

| | |
|--|--|
| CT | Effusions, pericardium, and epicardium |
| MRI | Effusions, pericardium, and epicardium |
| Pericardioscopy, pericardial/epicardial biopsy | Establishing the specific etiology |

*Typical lead involvement: I, II, aVL, aVF, and V3-V6. The ST segment is always depressed in aVR, frequently in V1, and occasionally in V2. Stage IV may not occur, and there are permanent T-wave inversions and flattenings. If an ECG is first recorded in stage III, pericarditis cannot be differentiated by ECG from diffuse myocardial injury, “biventricular strain,” or myocarditis. ECG in early repolarization is very similar to stage I. Unlike stage I, this ECG does not acutely evolve, and J-point elevations are usually accompanied by a slur, oscillation, or notch at the end of the QRS just before and including the J point (best seen with tall R and T waves—large in an early repolarization pattern). Pericarditis is likely if, in lead V6, the J point is greater than 25% of the height of the T-wave apex (using the PR segment as a baseline).

[†]A rise in cardiac muscle troponin I (cTnI) was detected in 38/118 patients (32.2%), more frequently in younger, male patients, with ST segment elevation and pericardial effusion at presentation. An increase beyond 1.5 ng/mL was rare (7.6%) and associated with CK-MB elevation. cTnI increase was not a negative prognostic marker for the incidence of recurrences, constrictive pericarditis, cardiac tamponade, or residual left ventricular dysfunction.

Data from references 2, 3, and 7 to 19.

CK-MB, creatine kinase-MB; CT, computed tomography; ECG, electrocardiogram; MRI, magnetic resonance imaging.

Electrocardiography demonstrates low QRS and T wave voltages, PR-segment depression (Fig. 84-1), ST segment/T wave changes, bundle branch block, and electrical alternans (rarely seen in the absence of tamponade).⁷ Microvoltage and electrical alternans are reversible after the drainage of the effusion and resolution of the inflammatory process.¹⁹ In chest radiography, large effusions are depicted as globular cardiomegaly with sharp margins (“water bottle” silhouette) (Fig. 84-2).¹² The size of effusions noted during echocardiography can be graded as (1) small (echo-free space in diastole <10 mm), (2) moderate (10 to 20 mm) (Fig. 84-3), (3) large (≥20 mm), or (4) very large (≥20 mm and compression of the heart). In large pericardial effusions, the heart may move freely within the pericardial

FIGURE 84-1 ■ Typical electrocardiographic changes in acute pericarditis: PR depression (small arrow) and concave ST-segment elevation (large arrow).

cavity (“swinging heart”), inducing pseudoprolapse and pseudosystolic anterior motion of the mitral valve, paradoxical motion of the interventricular septum, and midsystolic aortic valve closure (Table 84-2).³¹⁻⁴¹ Up to one-third of patients with an asymptomatic large pericardial chronic effusion develop unexpected cardiac tamponade.²¹ Triggers for tamponade include hypovolemia, paroxysmal tachyarrhythmia, and intercurrent acute pericarditis.

Constrictive Pericarditis

Constrictive pericarditis is a rare, but severely disabling, consequence of chronic inflammation of the pericardium, leading to impaired filling of the ventricles and reduced ventricular function. Until recently, increased pericardial thickness has been considered an essential diagnostic feature of constrictive pericarditis. However, in a large surgical series from the Mayo Clinic, constriction was present in 18% of patients with normal pericardial thickness.⁴² Tuberculosis, mediastinal irradiation, and previous surgical procedures are frequent.⁴³ Constrictive pericarditis may rarely develop only in the epicardial layer in patients with a previously removed parietal pericardium.⁴⁴ Transient constrictive pericarditis is an uncommon, but important, entity because pericardiectomy is not indicated in these patients.⁴⁵

Patients complain of fatigue, peripheral edema, breathlessness, and abdominal swelling, which may be aggravated by a protein-losing enteropathy. In decompensated patients, venous congestion, hepatomegaly, pleural effusions, and ascites may occur. Hemodynamic impairment can be additionally aggravated by systolic dysfunction due to myocardial fibrosis or atrophy. Differential diagnosis has to include acute dilatation of the heart, pulmonary embolism, right ventricular infarction, pleural effusion, chronic obstructive lung disease,⁴⁶ and restrictive cardiomyopathy. The best way to distinguish constrictive pericarditis from restrictive cardiomyopathy is by Doppler and/or tissue Doppler echocardiographic analysis of respiratory changes with or without changes in preload.⁴⁷ However, physical findings, an electrocardiogram (ECG), chest radiography (see Fig. 84-2, right), computed tomography (CT) (Fig. 84-4, left), magnetic resonance imaging (MRI) (see Fig. 84-4, right), hemodynamics, and endomyocardial biopsy may be helpful as well.⁷

FIGURE 84-2 ■ Chest radiographs in a patient with a very large pericardial effusion—“water bottle” sign (*left*)—and in a patient with constrictive pericarditis and pericardial calcifications (*white arrows, right*).

FIGURE 84-3 ■ Echocardiographic findings in a small to moderate pericardial effusion (*white arrows*). Long-axis parasternal view. Ao, aortic root; LA, left atrium; LV, left ventricle; RV, right ventricle.

Pericardiectomy is the only treatment for permanent constriction. The indications are based on clinical symptoms, echocardiographic findings, CT/MRI, and heart catheterization. A primary installation of cardiopulmonary bypass (CPB) is not recommended, as diffuse bleeding can occur following systemic heparinization. Pericardiectomy for constrictive pericarditis has a mortality rate of 6% to 12%,⁴⁸⁻⁵¹ and complete normalization of cardiac hemodynamics is reported in only 60% of patients.^{48,50} Major complications include acute perioperative cardiac insufficiency and ventricular wall rupture.⁵² Cardiac mortality and morbidity with pericardiectomy are mainly caused by the presence of myocardial atrophy or myocardial fibrosis that was not recognized before surgery.⁴³ The exclusion of patients with extensive myocardial fibrosis and/or atrophy has reduced the mortality rate of pericardiectomy to 5%. Postoperative low cardiac output⁵² should be treated by fluid substitution and catecholamines, high doses of digitalis, and intraaortic balloon pump, in the most severe cases. If indications for surgery are established early, long-term survival after pericardiectomy corresponds to that of the general population.^{49,50} However, if severe clinical symptoms are present for a longer period before surgery, even complete pericardiectomy may not achieve total restitution.

Pericardial Cysts

Congenital pericardial cysts are uncommon; they may be unilocular or multilocular, with a diameter ranging from 1 to 5 cm.⁵³ Inflammatory cysts comprise pseudocysts, as well as encapsulated and loculated pericardial effusions, caused by rheumatic pericarditis, bacterial infection (particularly tuberculosis), trauma, and cardiac surgery. Most patients are asymptomatic, and cysts are detected incidentally on chest radiographs as an oval, homogeneous radiodense lesion, usually at the right cardiophrenic angle.⁵⁴ However, patients can also present with chest discomfort, dyspnea, cough, or palpitations, owing to compression of the heart. Echocardiography is useful, but additional imaging by CT (density readings) or MRI is often needed.⁵⁵ Treatment of congenital and inflammatory cysts involves percutaneous aspiration and ethanol sclerosis.^{56,57} If this is not feasible, video-assisted thoracotomy or surgical resection may be necessary. Echinococcal cysts usually originate from ruptured hydatid cysts in the liver and lungs. Their surgical excision is not recommended; percutaneous aspiration and instillation of ethanol or silver nitrate after pretreatment with albendazole (800 mg/day for 4 weeks) is recommended instead.⁵⁷

SPECIFIC FORMS OF PERICARDITIS

Viral Pericarditis

Viral pericarditis is the most common infection of the pericardium. Inflammatory abnormalities are due to direct viral attack, the immune response (antiviral or anticardiac), or both.^{3,58} Early viral replication in pericardial and epimyocardial tissue elicits cellular and humoral immune responses against the virus and/or cardiac tissue. Deposits of immunoglobulin (Ig)M, IgG, and occasionally IgA can be found in the pericardium and myocardium for years.⁵⁸ Various viruses can cause pericarditis, including enteroviruses, echoviruses, adenoviruses, cytomegaloviruses, Epstein-Barr virus, herpes simplex, herpes humanus 6 (HHV6), influenzaviruses, parvovirus B19 (PVB19), hepatitis C, and human immunodeficiency virus (HIV). In the past few years, PVB19 and HHV6 have been increasing and entero-, echo-, and adenoviruses have been decreasing as causes; these trends have also been observed in myocarditis. Attacks of enteroviral pericarditis follow the seasonal epidemics of coxsackievirus A and B and echovirus infections.⁵⁹ Cytomegalovirus (CMV) pericarditis has an increased incidence in immunocompromised and HIV-infected hosts.⁶⁰ Infectious mononucleosis may also present as pericarditis.

Diagnosing viral pericarditis is not possible without evaluating pericardial effusion and/or pericardial/epicardial tissue, preferably by polymerase chain reaction (PCR) or in situ hybridization. A four-fold

TABLE 84-2 Diagnosis of Cardiac Tamponade

| | |
|---------------------------------------|---|
| Clinical presentation | Elevated systemic venous pressure,* hypotension, [†] pulsus paradoxus, [‡] tachycardia, [§] dyspnea, or tachypnea with clear lungs |
| Precipitating factors | Drugs (cyclosporine, anticoagulants, thrombolytics), recent cardiac surgery, indwelling instrumentation, blunt chest trauma, malignancies, connective tissue disease, renal failure, septicemia [†] |
| ECG | Can be normal or nonspecifically changed (ST-T wave), electrical alternans (QRS, rarely T), bradycardia (end stage), electromechanical dissociation (agonal phase) |
| Chest radiograph | Enlarged cardiac silhouette with clear lungs |
| M-mode/two-dimensional echocardiogram | Diastolic collapse of the anterior RV free wall, [†] RA collapse, LA and rarely LV collapse, increased LV diastolic wall thickness "pseudohypertrophy," IVC dilatation (no collapse in inspiration), "swinging heart" |
| Doppler | Tricuspid flow increases and mitral flow decreases during inspiration (reverse in expiration) Systolic and diastolic flows are reduced in systemic veins in expiration and reverse flow with atrial contraction is increased |
| M-mode color Doppler | Large respiratory fluctuations in mitral/tricuspid flows |
| Cardiac catheterization | Confirmation of the diagnosis and quantification of the hemodynamic compromise RA pressure is elevated (preserved systolic \times descent and absent or diminished diastolic γ descent) Intrapericardial pressure is also elevated and virtually identical to RA pressure (both pressures fall in inspiration) RV mid-diastolic pressure is elevated and equal to the RA and pericardial pressures (no dip-and-plateau configuration) Pulmonary artery diastolic pressure is slightly elevated and may correspond to the RV pressure Pulmonary capillary wedge pressure is also elevated and nearly equal to intrapericardial and right atrial pressure LV systolic and aortic pressures may be normal or reduced Documenting that pericardial aspiration is followed by hemodynamic improvement** Detection of coexisting hemodynamic abnormalities (LV failure, constriction, pulmonary hypertension) Detection of associated cardiovascular diseases (cardiomyopathy, coronary artery disease) |
| RV/LV angiography | Atrial collapse and small hyperactive ventricular chambers |
| Coronary angiography | Coronary compression in diastole |

*Jugular venous distention is less notable in hypovolemic patients or in "surgical tamponade." An inspiratory increase or lack of fall of pressure in the neck veins (Kussmaul sign), when verified by tamponade or after pericardial drainage, indicates effusive-constrictive disease.

[†]Heart rate is usually greater than 100 beats per minute but may be lower in patients with hypothyroidism or uremia.

[‡]Pulsus paradoxus is defined as a drop in systolic blood pressure greater than 10 mm Hg during inspiration, while diastolic blood pressure remains unchanged. It is easily detected by simply feeling the pulse, which diminishes significantly during inspiration. Clinically significant pulsus paradoxus is apparent when the patient is breathing normally. When this sign is present only in deep inspiration, it should be interpreted with caution. The magnitude of pulsus paradoxus is evaluated by sphygmomanometry. If pulsus paradoxus is present, the first Korotkoff sound is not heard equally well throughout the respiratory cycle but only during expiration at a given blood pressure. The blood pressure cuff is, therefore, inflated above the patient's systolic pressure. Then it is slowly deflated, while the clinician observes the phase of respiration. During deflation, the first Korotkoff sound is intermittent. Correlation with the patient's respiratory cycle identifies a point at which the sound is audible during expiration but disappears when the patient breathes in. As the cuff pressure drops further, another point is reached when the first blood pressure sound is audible throughout the respiratory cycle. The difference in systolic pressure between these two points is the clinical measure of pulsus paradoxus. Pulsus paradoxus is absent in tamponade complicating an atrial septal defect and in patients with significant aortic regurgitation.

[§]Occasional patients are hypertensive, especially if they have preexisting hypertension.

[†]Febrile tamponade may be misdiagnosed as septic shock.

[†]Right ventricular collapse can be absent in elevated right ventricular pressure and right ventricular hypertrophy or in right ventricular infarction.

**If after drainage of the pericardial effusion, the intrapericardial pressure does not fall below atrial pressure, effusive-constrictive disease should be considered.

IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Data from references 31 to 41.

FIGURE 84-4 ■ **Computed tomography findings in constrictive pericarditis (left).** White vertical arrows are depicting thickened pericardium and pericardial calcification. The magnetic resonance imaging results of a patient with effusive-constrictive pericarditis are shown in the right image. Horizontal arrows show a loculated pericardial effusion, and the vertical arrow shows thickened pericardium.

rise in serum antibody levels is suggestive, but not diagnostic, of viral pericarditis.

Treatment of viral pericarditis is directed toward resolving symptoms (see [Acute Pericarditis](#)), preventing complications, and eradicating the virus. In patients with chronic or recurrent symptomatic pericardial effusion and confirmed viral infection, the following specific treatments are under investigation⁶¹:

1. CMV pericarditis: hyperimmune globulin once per day 4 mL/kg on days 0, 4, and 8 and 2 mL/kg on days 12 and 16
2. Coxsackievirus B pericarditis: interferon alfa or interferon beta 2.5×10^6 IU/m² subcutaneously three times per week
3. Adenovirus, PVB19, and HHV6 perimyocarditis: immunoglobulin treatment with 20 g or more intravenously on days 1 and 3 for 6 to 8 hours, which may be repeated and combined with gancyclovir to become effective for virus elimination

Pericardial manifestations of HIV infection can be due to infective, noninfective, and neoplastic (Kaposi's sarcoma and/or lymphoma) diseases. Infective (myo)pericarditis results from local HIV infection and/or from other viral, bacterial (e.g., *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Mycobacterium avium*, *M. tuberculosis*), and fungal coinfections (*Cryptococcus neoformans*).⁶² In progressive disease, the incidence of echocardiographically detected pericardial effusion may be up to 40%.⁶³ Cardiac tamponade is rare.⁶⁴ During treatment with retroviral compounds, lipodystrophy can develop (best demonstrated by MRI), with intense paracardial fat deposition leading to heart failure. Treatment is generally symptomatic, whereas in large effusions and cardiac tamponade, pericardiocentesis is necessary. The use of corticosteroid therapy is contraindicated except in patients with secondary tuberculous pericarditis, as an adjunct to tuberculostatic treatment.⁶⁵

Bacterial Pericarditis

Purulent pericarditis in adults is rare but always fatal if not treated.⁶⁶⁻⁶⁹ The mortality rate in treated patients is 40%, mostly due to cardiac tamponade, toxicity, and constriction. It is usually a complication of an infection originating elsewhere in the body, arising by contiguous spread or hematogenous dissemination.⁷⁰ Predisposing conditions are pericardial effusion, immunosuppression, chronic diseases (e.g., alcohol abuse, rheumatoid arthritis), cardiac surgery, and chest trauma. The disease appears as an acute, fulminant infectious illness of short duration. Percutaneous pericardiocentesis must be promptly performed, and the obtained pericardial fluid should undergo Gram staining, acid-fast staining, and fungal staining, followed by cultures of the pericardial and body fluids. Rinsing of the pericardial cavity, combined with effective systemic antibiotic therapy, is mandatory (antistaphylococcal antibiotic plus aminoglycoside, followed by tailored antibiotic therapy according to the pericardial fluid and blood culture results).⁶⁷ Intrapericardial instillation of antibiotics (e.g., gentamicin) is useful but not sufficient. Frequent irrigation of the pericardial cavity with urokinase or streptokinase using large catheters may liquefy the purulent exudate,^{68,69} but open surgical drainage through a subxiphoid pericardiectomy is preferable.⁶⁶ Pericardiectomy is required in patients with dense adhesions, a loculated and thick purulent effusion, recurrence of tamponade, persistent infection, and progression to constriction.⁶⁷ Surgical mortality is up to 8%.

Tuberculous Pericarditis

In the past decade, tuberculous pericarditis in developed countries has been primarily seen in immunocompromised patients, such as those with acquired immunodeficiency syndrome (AIDS).⁷¹ The mortality rate in untreated effusive tuberculous pericarditis approaches 85%. Pericardial constriction occurs in 30% to 50% of patients.^{72,73}

The clinical presentation is variable: acute pericarditis with or without effusion; cardiac tamponade; silent, often large pericardial effusion with a relapsing course; toxic symptoms with persistent fever; acute constrictive pericarditis; subacute constriction; effusive-

FIGURE 84-5 ■ Flexible percutaneous pericardioscopy and epicardial biopsy (arrow).

constrictive or chronic constrictive pericarditis; and pericardial calcifications.^{3,74} The diagnosis is made by identification of *M. tuberculosis* in the pericardial fluid or tissue and/or the presence of caseous granulomas in the pericardium.⁷¹ Importantly, PCR can identify the DNA of *M. tuberculosis* rapidly from only 1 μ L of pericardial fluid.^{75,76} Increased adenosine deaminase activity and interferon gamma concentration in pericardial effusion are also diagnostic, with a high sensitivity and specificity. Both pericardioscopy and pericardial biopsy have also improved the diagnostic accuracy for tuberculous pericarditis (Fig. 84-5).¹⁵ Pericardial biopsy enables rapid diagnosis with better sensitivity than pericardiocentesis (100% vs. 33%).

Pericarditis in a patient with proven extracardiac tuberculosis is strongly suggestive of a tuberculous etiology (several sputum cultures should be taken).⁷⁷ The tuberculin skin test may be falsely negative in 25% to 33% of tests⁷² and falsely positive in 30% to 40% of patients.⁷¹ The more accurate enzyme-linked immunospot test detects T cells specific for *M. tuberculosis* antigen.⁷⁸ Perimyocardial tuberculous involvement is also associated with high serum titers of antimyolemmal and antimyosin antibodies.⁷⁹ The diagnostic yield of pericardiocentesis in tuberculous pericarditis ranges from 30% to 76% according to methods used for analyzing pericardial effusions.^{72,75} Pericardial fluid demonstrates high specific gravity, high protein levels, and a high white blood cell count (from 0.7 to 54×10^9 /L).⁷¹

Various antituberculous drug combinations of different durations (6, 9, or 12 months) have been used.^{71,72,77,80-83} Prevention of constriction in chronic pericardial effusion of undetermined etiology by “ex iuvantibus” antitubercular treatment was not successful.⁸⁰ The use of corticosteroids remains controversial.^{77,81-84} A meta-analysis of patients with effusive and constrictive tuberculous pericarditis^{82,83} suggested that tuberculostatic treatment combined with corticosteroids might be associated with fewer deaths and less frequent need for pericardiocentesis or pericardiectomy.^{77,85} If given, prednisone should be administered in relatively high doses (1 to 2 mg/kg/day) because rifampicin induces its liver metabolism.⁷ This dose is maintained for 5 to 7 days and progressively reduced in 6 to 8 weeks. If constriction develops despite combination therapy, pericardiectomy is indicated.

Pericarditis in Renal Failure

Renal failure is a common cause of pericardial disease, producing large pericardial effusions in up to 20% of patients.⁸⁶ Two forms have been described:

1. Uremic pericarditis: this occurs in 6% to 10% of patients with advanced renal failure (acute or chronic) before dialysis has

been instituted or shortly thereafter.⁸⁷ It results from inflammation of the visceral and parietal pericardium and correlates with the degree of azotemia (blood urea nitrogen > 60 mg/dL).

2. Dialysis-associated pericarditis: this occurs in up to 13% of patients on maintenance hemodialysis⁸⁸ and occasionally with chronic peritoneal dialysis. It is due to inadequate dialysis and/or fluid overload.⁸⁹ Pathologic examination of the pericardium shows adhesions between the thickened pericardial membranes ("bread and butter" appearance). The clinical features may include transient pericardial rubs, fever, and pleuritic chest pain, but many patients are asymptomatic. Because of autonomic impairment in uremic patients, the heart rate may remain slow (60-80 beats/min) during tamponade, despite fever and hypotension. Anemia, due to induced resistance to erythropoietin, may worsen the clinical picture.⁹⁰ The ECG may not show the typical diffuse ST segment/T wave elevations observed with other causes of acute pericarditis, owing to a lack of myocardial inflammation.⁹¹ If the ECG is typical of acute pericarditis, intercurrent infection must be suspected.

Most patients with uremic pericarditis respond rapidly to hemodialysis or peritoneal dialysis with resolution of chest pain and the pericardial effusion. To avoid hemopericardium, heparin-free hemodialysis should be used. Hypokalemia and hypophosphatemia should be prevented by supplementing the dialysis solution when appropriate.⁹² Intensified dialysis usually leads to resolution of the pericarditis within 1 to 2 weeks.⁹³ Peritoneal dialysis, which does not require heparinization, may be therapeutic in pericarditis resistant to hemodialysis or if heparin-free hemodialysis cannot be performed. NSAIDs and systemic corticosteroids have limited success when intensive dialysis is ineffective.⁹⁴ Cardiac tamponade and large chronic effusions resistant to dialysis must be treated with pericardiocentesis. Large, nonresolving symptomatic effusions should be treated with intrapericardial instillation of corticosteroids after pericardiocentesis or subxiphoid pericardiectomy (triamcinolone hexacetonide 50 mg every 6 hours for 2-3 days).^{88,94} Pericardiectomy is indicated only in severely symptomatic patients refractory to other treatment owing to its potential morbidity and mortality. After renal transplantation, pericarditis has also been reported in 2.4% of patients.⁹⁵ Uremia or infection (CMV) may be the causes.

Autoreactive Pericarditis and Pericarditis in Systemic Autoimmune Diseases

The diagnosis of autoreactive pericarditis is established using the following criteria²:

1. Pericardial fluid containing increased number of lymphocytes, as well as mononuclear cells greater than 5000/mm³ (autoreactive lymphocytic) or antibodies (e.g., antisarcolemmal) against heart muscle tissue (autoreactive antibody mediated)
2. Inflammation in epicardial/endomyocardial biopsy samples of more than 14 cells/mm²
3. Exclusion of active viral infection both in the pericardial effusion and endomyocardial/epimyocardial biopsy samples (no virus isolation, no IgM-titer against cardiotropic viruses in the pericardial effusion, and PCR negative for major cardiotropic viruses)
4. Tuberculosis, *Borrelia burgdorferi*, *Chlamydia pneumoniae*, and other bacterial infections excluded by PCR and/or cultures
5. Neoplastic infiltration absent in the pericardial effusion and biopsy samples
6. Exclusion of systemic metabolic disorders and uremia

For autoreactive pericarditis, intrapericardial treatment with triamcinolone is effective, with rare side effects.

Pericarditis occurs in many systemic autoimmune diseases: rheumatoid arthritis, systemic lupus erythematosus, progressive systemic sclerosis, polymyositis/dermatomyositis, mixed connective tissue disease, seronegative spondyloarthropathies, systemic and hypersensitivity vasculitides, Behçet's syndrome, Wegener's granulomatosis, and

sarcoidosis.⁷ Intensified treatment of the underlying disease and symptomatic management are indicated.

The Postcardiac Injury Syndrome: Postpericardiectomy Syndrome

Postcardiac injury syndrome develops within days to months after cardiac injury, pericardial injury, or both.^{7,96,97} It resembles postmyocardial infarction syndrome, with both conditions appearing to be variants of a common immunopathologic process. Pericardial effusion also occurs after orthotopic heart transplantation (21% of patients). It is more frequent in patients receiving aminocaproic acid during the operation.⁹⁸ Cardiac tamponade after open heart surgery is more common after valve surgery than after coronary artery bypass grafting and may be related to the preoperative use of anticoagulants.⁹⁹

Warfarin administration in patients with early postoperative pericardial effusion imposes the greatest risk, particularly in those who did not undergo pericardiocentesis and drainage of the effusion.¹⁰⁰ Symptomatic treatment is generally the same as in acute pericarditis (NSAIDs or colchicine for several weeks or months¹⁰¹), but this has been questioned recently.¹⁰² In patients undergoing cardiac surgery, perioperative use of colchicine compared with placebo reduced the incidence of postpericardiectomy syndrome but with an increased rate of gastrointestinal adverse effects.¹⁰³ Long-term (3 to 6 months) oral corticosteroids, or preferably pericardiocentesis and intrapericardial instillation of triamcinolone (300 mg/m²), are therapeutic options in refractory forms. Redo surgery is rarely needed.

Postinfarction Pericarditis

Two forms of postinfarction pericarditis can be distinguished: an "early" form (pericarditis episternocardiaca) and a "delayed" form (Dressler's syndrome).¹⁰⁴ Episternocardiaca pericarditis, caused by direct exudation, occurs in 5% to 20% of transmural myocardial infarctions but is rarely discovered clinically. Dressler's syndrome occurs from 1 week to several months after myocardial infarction and has symptoms and manifestations similar to those of postcardiac injury syndrome. It does not require a transmural infarction,¹⁰⁵ and it can also appear as an extension of episternocardiaca pericarditis. Its incidence is 0.5% to 5%¹⁰⁶ and is lower still in patients treated with thrombolytics (<0.5%)¹⁰⁷ but more frequent in cases of pericardial bleeding after antithrombotic treatment.^{104,108} Of note, ECG changes are often overshadowed by myocardial infarction changes. Stage one ECG changes are uncommon and suggest "early" postmyocardial infarction syndrome, whereas failure to evolve or "resurrection" of previously inverted T waves strongly suggests myocardial infarction pericarditis.^{109,110} Postinfarction pericardial effusion greater than 10 mm is most frequently associated with hemopericardium, and two-thirds of these patients may develop tamponade/free wall rupture.¹¹¹ Urgent surgical treatment is lifesaving. If immediate surgery is not available or contraindicated, pericardiocentesis and intrapericardial fibrin glue instillation could be an alternative in subacute tamponade.^{111,112} Ibuprofen, which increases coronary flow, is the agent of choice.¹¹³ Aspirin, up to 650 mg every 4 hours for 2 to 5 days, has also been successfully applied. Corticosteroids can be used for refractory symptoms but may delay healing after the infarction.⁷

Traumatic Pericardial Effusion and Hemopericardium in Aortic Dissection

Direct pericardial injury can be induced by accidents or iatrogenic wounds.¹¹⁴⁻¹¹⁷ Iatrogenic tamponade occurs most frequently in percutaneous mitral valvuloplasty, during or after transeptal puncture, particularly if no biplane catheterization laboratory is available and a small left atrium is present. Whereas puncture of the interatrial septum is asymptomatic, passage through the free wall induces immediate chest pain. If high-pressure-containing structures are punctured, rapid deterioration occurs. However, if only the atrial wall is perforated, tamponade may be delayed for 4 to 6 hours. Rescue

pericardiocentesis is successful in 95% to 100% of cases, with less than 1% mortality.¹¹⁸

Transection of the coronary artery and acute or subacute cardiac tamponade occur very rarely during percutaneous coronary interventions.^{119,120} A breakthrough in the treatment of coronary perforation has been the development of membrane-covered graft stents.^{121,122}

During right ventricular endomyocardial biopsy, the catheter may pass through the myocardium, particularly when the bioprobe has not been opened before reaching the endocardial border or has been directed toward the right ventricular free wall instead of toward the septum. Frank cardiac perforations are accompanied by sudden bradycardia and hypotension.¹²³ Perforation rates of 0.3% to 5% have been reported, leading to tamponade and circulatory collapse in less than half of cases.¹²³⁻¹²⁵ The incidence of pericardial hemorrhage with left ventricular endomyocardial biopsy is lower (0.1%-3.3%). Severe complications, leading to procedure-related mortality, were reported in only 0.05% of more than 6000 cases in a worldwide survey¹²⁴ and in none of the 2537 patients at our center.¹²⁵

Pacemaker leads penetrating the right ventricle or epicardial electrodes may cause pericarditis with tamponade, adhesions, or constriction.¹²⁶⁻¹²⁹ A right bundle branch block instead of the usual left bundle branch block is a clue that this has occurred.

Blunt chest trauma is a major risk of motor vehicle accidents. The deceleration force can lead to myocardial contusion with intrapericardial hemorrhage, cardiac rupture, pericardial rupture, or herniation. Transesophageal echocardiography or immediate CT should be performed.^{130,131} Pericardial laceration and partial extrusion of the heart into the mediastinum and pleural space may also occur after injury.¹¹⁵

In dissection of the ascending aorta, pericardial effusion can be found in 17% to 45% of patients and 48% of autopsy cases.¹³⁰ In a clinical series of aortic dissection, pericardial tamponade was found by CT,¹³¹ MRI,¹³² or echocardiography¹³³ in 17% to 33% of patients with type I dissection, 18% to 45% with type II dissection, and 6% with type III dissection.¹³¹ Pericardiocentesis is contraindicated, owing to the risk of intensified bleeding and extension of the dissection.^{134,135} Surgery should be performed immediately.

Neoplastic Pericarditis

Primary tumors of the pericardium are 40 times less common than metastatic ones.⁷ Mesothelioma, the most common primary tumor, is almost always incurable. The most common secondary malignant tumors are lung cancer, breast cancer, malignant melanoma, lymphoma, and leukemia. Effusions may be small or large with imminent tamponade (frequent recurrences) or constriction. Tamponade may even be the initial sign of malignant disease.¹³⁶ With small effusions, most patients are asymptomatic. The onset of dyspnea, cough, chest pain, tachycardia, and jugular venous distention is observed when the volume of fluid exceeds 500 mL. Pulsus paradoxus, hypotension, cardiogenic shock, and paradoxical movement of the jugular venous pulse are important signs of cardiac tamponade. The diagnosis is based on confirmation by cytology or biopsy of malignant infiltration within the pericardium. Of note, in almost two-thirds of patients with documented malignancy, pericardial effusion is caused by nonmalignant diseases (e.g., radiation pericarditis, opportunistic infections).^{137,138} The chest radiograph, CT, and MRI may reveal mediastinal widening, a hilar mass, or pleural effusion.⁷ The analysis of pericardial fluid and pericardial or epicardial biopsy is essential for the confirmation of malignant pericardial disease.

Cardiac tamponade is an absolute indication for pericardiocentesis. In suspected neoplastic pericardial effusion without tamponade, systemic antineoplastic treatment as baseline therapy can prevent recurrences in up to 67% of cases.¹³⁶ However, pericardial drainage is recommended in all patients with large effusions because of the high recurrence rate (40%-70%).¹¹⁰⁻¹⁴⁶ Prevention of recurrences may be achieved by intrapericardial instillation of sclerosing agents, cytotoxic agents, or immunomodulators. Intrapericardial treatment tailored to the type of the tumor indicates that administration of cisplatin is

effective in secondary lung cancer, and intrapericardial instillation of thiotepa appears to be highly effective in breast cancer pericardial metastases.¹⁴⁷⁻¹⁵² No patient in these studies showed signs of constrictive pericarditis. Tetracyclines as sclerosing agents also control malignant pericardial effusions in around 85% of cases, but side effects and complications are quite frequent: fever (19%), chest pain (20%), and atrial arrhythmias (10%).^{136,145,146} Although intrapericardial administration of radionuclides has yielded very good results, it is not widely accepted because of the logistic problems connected with radioactivity.¹⁵³ Radiation therapy is very effective (93%) in controlling malignant pericardial effusions in patients with radiosensitive tumors, such as lymphoma and leukemia. However, radiotherapy of the heart itself can cause myocarditis and pericarditis.¹³⁶

RARE FORMS OF PERICARDIAL DISEASE

Fungal pericarditis occurs mainly in immunocompromised patients or in the course of endemic, acquired fungal infections.¹⁵⁴ It is due to endemic (*Histoplasma*, *Coccidioides*) or opportunistic fungi (*Candida*, *Aspergillus*, *Blastomyces*) and semifungi (*Nocardia*, *Actinomyces*).¹⁵⁵⁻¹⁵⁷ Diagnosis is obtained by staining and culturing pericardial fluid or tissue. Antifungal antibodies in serum are also helpful in establishing the diagnosis.³ Treatment with fluconazole, ketoconazole, itraconazole, amphotericin B, liposomal amphotericin B, or amphotericin B lipid complex is indicated. NSAIDs can support the treatment with antifungal drugs. Patients with histoplasmosis pericarditis do not need antifungal therapy but respond to NSAIDs given for 2 to 12 weeks. Sulfonamides are the drugs of choice for nocardiosis. A combination of three antibiotics, including penicillin, should be given for actinomycosis. Pericardiocentesis or surgical treatment is indicated for hemodynamic impairment. Pericardiectomy is indicated in fungal constrictive pericarditis.

Radiation pericarditis may begin during exposure (very rare) or months to years later, with a latency of up to 15 to 20 years. Its occurrence is influenced by the applied source, dose, fractionation, duration, radiation-exposed volume, form of mantle field therapy, and age of the patient.¹⁵⁸ The effusion may be serous or hemorrhagic, later on with fibrinous adhesions or constriction; it is typically without tissue calcification. The symptoms may be masked by the underlying disease or chemotherapy. Imaging should start with echocardiography, followed by cardiac CT or MRI, if necessary. Pericarditis without tamponade may be treated conservatively, but effusions respond favorably to intrapericardial triamcinolone instillation. Pericardiocentesis and fluid analysis can rule out neoplastic progression to the pericardium.¹⁵⁹ Pericardial constriction occurs in up to 20% of patients, requiring pericardiectomy. Operative mortality is high (21%) and postoperative 5-year survival is poor (1%), mostly because of myocardial fibrosis.¹⁶⁰

Chylopericardium refers to a communication between the pericardium and thoracic duct. It may be the result of trauma, congenital anomalies, complications of open-heart surgery,¹⁶¹ mediastinal lymphangiomas, lymphangiomatous hamartomas, lymphangiectasis, and obstruction or anomalies of the thoracic duct.¹⁶² Infection, tamponade, or constriction may aggravate the prognosis.¹⁶³ The pericardial fluid is sterile, odorless, and opalescent, with a milky white appearance and the microscopic finding of fat droplets. The chylous nature of the fluid is confirmed by its alkaline reaction, specific gravity between 1010 and 1021, Sudan III stain for fat, and high concentrations of triglycerides (5 to 50 g/L) and protein (22 to 60 g/L).^{164,165} Enhanced CT, alone or combined with lymphography, can identify not only the location of the thoracic duct but also its lymphatic connection to the pericardium.^{166,167}

Treatment depends on the etiology and amount of chylous accumulation.¹⁶⁸ Chylopericardium after thoracic or cardiac operations is preferably treated by pericardiocentesis and diet (medium-chain triglycerides).^{169,170} If further production of chylous effusion continues, surgical treatment is mandatory. When conservative treatment and pericardiocentesis fail, creation of a pericardioperitoneal window is a reasonable option.^{171,172} Alternatively, when the course of the thoracic

duct is precisely identified, its ligation and resection just above the diaphragm is the most effective treatment.¹⁷³

Drug- and toxin-related pericarditis, tamponade, adhesions, fibrosis, or constriction may be induced by several drugs.^{7,174} Mechanisms include drug-induced lupus reactions, idiosyncrasy, “serum sickness,” foreign substance reactions, and immunopathy. Management is based on discontinuation of the causative agent and symptomatic treatment.

Pericardial effusion in hypothyroidism occurs in 5% to 30% of patients.⁷ Fluid accumulates slowly, and tamponade occurs rarely. In some cases, cholesterol pericarditis may be observed. The diagnosis is based on serum levels of thyroxine and thyroid-stimulating hormone. Bradycardia, low QRS voltage and T-wave inversion or flattening on the ECG, cardiomegaly on a chest radiograph, and pericardial effusion on echocardiography, as well as a history of radiation-induced thyroid dysfunction, myopathy, ascites, pleural effusion, and uveal edema, may be observed.¹⁷⁵⁻¹⁷⁹ Therapy with thyroid hormone decreases the pericardial effusion.

Pericardial effusion and constriction in pregnancy may manifest as a minimal to moderate, clinically silent hydropericardium by the third trimester. Cardiac compression is rare.¹⁸⁰ ECG changes of acute pericarditis in pregnancy should be distinguished from the slight ST segment depression and T wave changes seen in normal pregnancy.^{180,181} Occult constriction becomes manifest in pregnancy because of the increased blood volume.¹⁸¹ Most pericardial disorders are managed as in nonpregnant women.^{182,183} However, caution is necessary because high-dose aspirin may prematurely close the ductus arteriosus, and colchicine is contraindicated in pregnancy. Pericardiotomy and pericardiectomy can be safely performed if necessary and do not impose a risk for subsequent pregnancies.^{183,184}

Fetal pericardial fluid can be detected by echocardiography after 20 weeks' gestation and is normally 2 mm or less in depth. A greater amount of fluid should raise questions about the possibility of Rh disease (hydrops fetalis), neoplasia, hypoalbuminemia, immunopathy, or maternally transmitted mycoplasmal or other infections.¹⁸⁵

KEY POINTS

1. The diagnosis of acute pericarditis is based on clinical presentation (chest pain, pericardial friction rub) and typical four-stage ECG changes. For etiologic diagnosis, pericardiocentesis, pericardioscopy, and pericardial/epicardial biopsy may be necessary.
2. Echocardiography is essential in all patients with pericarditis to detect pericardial effusion and determine its physiologic significance, as well as to check for signs of constriction, concomitant heart disease, or paracardial pathology.
3. A large proportion of patients usually classified as having “idiopathic” pericarditis actually have viral and autoreactive pericarditis. The diagnosis of viral pericarditis is not possible without the evaluation of pericardial effusion and/or pericardial/epicardial tissue, preferably by polymerase chain reaction (PCR) or in situ hybridization.
4. PCR identification of *Mycobacterium tuberculosis*, high adenosine deaminase activity, and interferon gamma concentration in pericardial effusion are diagnostic with a high sensitivity and specificity for tuberculous pericarditis.
5. Pericardiocentesis is indicated for cardiac tamponade; for a high suspicion of purulent, tuberculous, or neoplastic pericarditis; or in patients with a very large effusion without signs of tamponade (>20 mm in echocardiography in diastole). Electrical alternans and pulsus paradoxus are clinically important signs of the advanced stages of cardiac tamponade and indicate the need for prompt pericardial drainage.
6. Aortic dissection is a major contraindication to pericardiocentesis. Relative contraindications include uncorrected coagulopathy; anticoagulant therapy; thrombocytopenia less than 50,000/mm³; and small, posterior, and loculated effusions.
7. In cardiac wounds, postinfarction myocardial rupture, or dissecting aortic hematoma, emergency cardiac surgery is lifesaving. Loculated effusions may require open surgery or thoracoscopic drainage.
8. Postinfarction pericardial effusions larger than 10 mm in diastole are frequently associated with cardiac rupture. Urgent surgical treatment is indicated.
9. Intrapericardial instillation of antineoplastic (e.g., cisplatin, thiopeta) and/or sclerosing agents (e.g., gentamycin) can prevent recurrences of neoplastic pericardial effusions. Intrapericardial instillation of triamcinolone is highly effective in preventing recurrences in patients with autoreactive pericardial effusion and avoids the adverse effects of systemic corticosteroid therapy.
10. Pericardiectomy is the only treatment for permanent constrictive pericarditis. However, surgery should not be performed too early to avoid operating on patients with transient constriction. Even more important is not to perform surgery too late or in patients with myocardial fibrosis and/or atrophy. If indications for surgery are established early enough, long-term survival after pericardiectomy corresponds to that of the general population.

In the critical care setting, there are two distinct presentations of valvular heart disease: acute valve dysfunction resulting in acute heart failure and chronic valve disease with decompensation due to increased metabolic demands (Table 85-1).¹ Valve regurgitation is the most common type of acute valve dysfunction. Valve stenosis, with rare exceptions, is a chronic, slowly progressive disease. However, in patients with asymptomatic chronic valve stenosis, acute deterioration can occur if there is a superimposed hemodynamic burden. For example, patients with previously asymptomatic mitral stenosis may present with pulmonary edema in the setting of a systemic infection. Another example is an elderly adult with asymptomatic aortic stenosis who presents with cardiogenic shock in the setting of acute gastrointestinal bleeding. Prosthetic valve dysfunction, particularly mechanical valve thrombosis, can also present emergently.

The key concepts in the management of a critically ill patient with valvular heart disease are the use of echocardiography to provide an accurate diagnosis of disease severity and the appropriate use of invasive hemodynamic monitoring to optimize loading conditions. Handheld echocardiography may provide clues to the presence of valve disease but does not replace the need for a complete diagnostic study when this diagnosis is suspected. With acute valve regurgitation or prosthetic valve thrombosis, urgent surgical intervention can be life-saving. In critically ill patients who are poor surgical candidates, novel percutaneous valve interventions may be useful.

■ MITRAL REGURGITATION

Etiology

Mitral regurgitation may be caused by disease or the distortion of any component of the mitral valve apparatus—the mitral annulus, leaflets, chordae, and papillary muscles—as well as by alterations in left ventricular (LV) geometry or systolic function (Fig. 85-1).² Primary causes of chronic mitral regurgitation include myxomatous valve leaflets (mitral valve prolapse) and rheumatic disease. Chronic secondary mitral regurgitation may be due to dilated cardiomyopathy or coronary artery disease with regional or global LV dysfunction. The management of mitral regurgitation frequently differs between primary and secondary causes, making the identification of the correct etiology essential during evaluation.

Acute mitral regurgitation may also be due to the involvement of the valve leaflets or the left ventricle. Patients with myxomatous mitral valve disease may develop acute regurgitation due to spontaneous chordal rupture.³ Bacterial endocarditis results in acute mitral regurgitation due to the destruction of valve tissue, often with leaflet perforation. Moderate to severe mitral regurgitation due to papillary muscle involvement or regional myocardial dysfunction complicates 12% of acute myocardial infarctions and is associated with an increased risk of heart failure or death.⁴

Clinical Presentation

Although patients with chronic mitral regurgitation may be asymptomatic for many years, the regurgitant lesions impose a volume load on the left ventricle because an increased total stroke volume is needed to maintain a normal forward cardiac output. LV volume overload

results in progressive LV dilation and may lead to an irreversible decline in ventricular contractility, even in the absence of clinical symptoms. The evaluation of ventricular contractility is problematic in patients with mitral regurgitation, given that the measures of ventricular performance are affected by preload and afterload.⁵ However, based on outcomes after mitral valve surgery, the empiric parameters of ventricular end-systolic dimension and ejection fraction can be used to optimize the timing of surgical intervention. Thus, patients with moderate to severe chronic regurgitation undergo periodic echocardiography, with valve repair or replacement recommended when the end-systolic dimension is ≥ 40 mm and the ejection fraction is $\leq 60\%$.⁶

Chronic mitral regurgitation is usually well tolerated even when there is a superimposed hemodynamic load such as systemic infection, pregnancy, or trauma. However, mitral regurgitant severity may acutely worsen by at least two mechanisms. An increase in afterload, for example, with a hypertensive crisis, may increase regurgitant severity due to an increased driving pressure from the left ventricle to the left atrium. An alteration in the LV geometry, for example, with ventricular dilation due to decompensated heart failure, may change the orientation of the papillary muscles such that leaflet closure is impaired, resulting in a larger regurgitant orifice area.⁷ In this situation, a vicious cycle may ensue where LV dilation worsens mitral regurgitant severity, which increases LV dilation.

Acute mitral regurgitation presents with acute pulmonary edema and is a surgical emergency (Figs. 85-2 and 85-3). Mitral chordal rupture results in the acute presentation of heart failure, often in patients unaware of the diagnosis of mitral valve prolapse. Patients with mitral valve perforation due to endocarditis present with pulmonary edema superimposed on the signs and symptoms of endocarditis. Papillary muscle rupture or dysfunction after myocardial infarction (MI) usually presents several days after acute MI; in some cases, the initial presentation is of acute pulmonary edema, with the MI being clinically silent.

Diagnosis

A high level of clinical suspicion is needed to make a diagnosis of acute mitral regurgitation (Table 85-2). Acute pulmonary edema often obscures the signs and symptoms of the underlying disease process. The classical finding is a holosystolic murmur at the apex, radiating to the axilla. Although there is some correlation between murmur loudness and regurgitant severity with chronic regurgitation, the murmur may be soft with acute severe mitral regurgitation. In patients with severe mitral regurgitation after MI, a murmur cannot be appreciated in up to 50% of patients.

Thus, in patients presenting with acute pulmonary edema or cardiogenic shock, prompt echocardiography is essential. Transthoracic images are often diagnostic, allowing the identification of the etiology of valve dysfunction, quantitation of regurgitant severity, estimation of pulmonary pressures, and measurement of ventricular size and systolic function. If transthoracic images are nondiagnostic, transesophageal echocardiography (TEE) can be performed at the bedside in the intensive care unit (ICU). TEE provides excellent images of valve anatomy and the Doppler evaluation of valve function.

Other diagnostic tests are based on the clinical presentation. Multiple blood cultures should be obtained in febrile patients with systemic

or pulmonary edema to exclude the possibility of endocarditis. In patients with an abnormal electrocardiogram (ECG), chest pain, or a history of coronary artery disease, coronary angiography may be needed.

In patients with acute pulmonary edema or cardiogenic shock after MI, the differential diagnosis includes acute mitral regurgitation, a ventricular septal defect, or a contained rupture of the ventricular free wall. All these possibilities can be diagnosed by echocardiography in an experienced center.

When imaging is nondiagnostic or discrepant with clinical findings, invasive hemodynamic monitoring with a Swan-Ganz catheter for the measurement of pulmonary pressure and cardiac output may

FIGURE 85-1 ■ Mitral valve anatomy: mitral annulus, anterior and posterior leaflets, chordae tendineae, and papillary muscles. Mitral regurgitation may be due to a disease that primarily affects the valve leaflets (e.g., mitral valve prolapse, rheumatic mitral valve disease) or may result from alterations in the function or structure of the left ventricle, such as those induced by ischemic disease or dilated cardiomyopathy. (From Otto CM. Clinical practice. Evaluation and management of chronic mitral regurgitation. *N Engl J Med* 2001;345:740–746.)

FIGURE 85-2 ■ Two-dimensional transesophageal echocardiogram (A) in a 72-year-old male with known mitral valve prolapse; ruptured chordae resulted in flail of the mitral posterior leaflet (arrow) and acute worsening of symptoms. Color Doppler (B) shows severe eccentric mitral regurgitation with a mosaic pattern through the noncoapting mitral valve. AO, aorta; LA, left atrium; LV, left ventricle.

FIGURE 85-3 ■ Three-dimensional (3D) echocardiography of the same patient as in Fig. 85-2 in both diastole (**A**) and systole (**B**). 3D imaging provided a “surgeon’s view,” allowing instant viewing of the mitral valve en-face to assist operative planning for potential repair. In systole, the posterior leaflet (p) can be seen to prolapse above the anterior (a) leaflet, and ruptured chordae with flail segments can be seen (white arrow). AO, aorta; LAA, left atrial appendage; MV, mitral valve; TV, tricuspid valve.

BOX 85-1

Therapeutic Approach to Acute Valve Dysfunction

1. Accurate diagnosis with echocardiography; differentiates acute valve dysfunction from acute decompensation with chronic valve disease
2. Treat the underlying disease process associated with decompensation (endocarditis, acute myocardial infarction, anemia, etc.).
3. Optimize loading conditions using diuretics, vasodilators, and other agents with invasive hemodynamic monitoring.
4. Consult the cardiac surgery team as soon as the diagnosis is made.
5. Intraaortic balloon pump for acute mitral regurgitation.
6. Consider surgical or percutaneous intervention.

be considered in patients with suspected acute mitral regurgitation. At the time of placement, oxygen saturations in the right atrium, right ventricle, and pulmonary artery should be measured. A ventricular septal defect results in a “step-up” in oxygen saturation between the right atrium and ventricle secondary to oxygenated blood from the left ventricle entering the right ventricle. The pulmonary artery balloon-occluded (wedge) pressure tracing should be examined for the presence of a giant “v-wave,” which supports the diagnosis of acute mitral regurgitation but is not always present.

Management

In patients with chronic mitral regurgitation and heart failure, management is directed at treating the process leading to decompensation and optimizing loading conditions (Box 85-1). For example, in a patient with a systemic infection, treating the infection, controlling fever and tachycardia, and invasive monitoring to optimize preload and afterload are utilized. Medical therapy typically includes afterload reduction with nitroprusside or other vasodilators and preload reduction with diuretics.^{8,9} The goal is to support the patient through the period of decompensation. Typically, hemodynamics returns to the baseline-compensated state after the acute illness.

In contrast, acute severe mitral regurgitation is a surgical emergency. Mortality is extremely high without the restoration of valve competence; even with prompt valve surgery, the 30-day mortality is 23%.¹⁰ Medical stabilization should occur concurrently with consultation by a cardiac surgeon. Acutely, the placement of an intraaortic balloon pump (IABP) provides optimal afterload reduction while improving diastolic coronary blood flow.

The timing and risk of surgical intervention depend on the etiology of acute mitral regurgitation. Spontaneous chordal rupture can usually be treated early with mitral valve repair. Compared to valve replacement, mitral valve repair is associated with a lower operative mortality, improved preservation of LV function, and better long-term survival. In addition, the risks of a prosthetic valve and anticoagulation are avoided.

The timing of surgery for endocarditis depends on the disease course in that individual, but most centers now advocate early surgical intervention in patients with heart failure or severe valve regurgitation to prevent progressive valve damage and paravalvular abscess formation.^{11,12} In a large prospective multicenter study, early surgery was associated with a lower mortality than medical therapy (12% versus 21%).¹³ Valve repair is preferred but may not be possible, depending on the extent of tissue destruction. Early surgery is particularly beneficial in patients with paravalvular complications or systemic embolization.¹⁴

In patients with acute ischemic mitral regurgitation, treatment depends on the exact etiology of valve dysfunction.¹⁵ In patients with acute mitral regurgitation due to a regional wall-motion abnormality, myocardial function and mitral regurgitation may improve after percutaneous revascularization.¹⁶ In these patients, the use of an IABP and medical therapy may be advantageous during the acute episode, with weaning of therapy as myocardial function improves.

Mitral regurgitation due to partial or complete papillary muscle rupture requires surgical intervention. Although the risk of surgery is high, with an operative mortality rate of about 50%, the outcome is worse with medical therapy, with a mortality of 75% at 24 hours and 95% within 2 weeks after complete papillary muscle rupture.¹⁷ With the use of echocardiography, partial papillary muscle rupture can be recognized; prognosis in these patients depends on the extent of myocardial damage and severity of mitral regurgitation.¹⁸ With partial papillary muscle rupture, some surgeons prefer to stabilize the patient and delay surgery for 6 to 8 weeks after MI to avoid operating on the necrotic myocardial tissue. However, many patients cannot be stabilized, so acute intervention must be considered. Again, valve repair is preferred, but myocardial necrosis may necessitate valve replacement. Risk factors of surgery include older age, female gender, and poor LV systolic function.

In some patients, the risk of surgical intervention may be so high, such that it is futile. Less invasive transcatheter mitral valve repair may be an option in these situations (Table 85-3). MitraClip, the most widely used device, reduces mitral regurgitation by approximating the

TABLE 85-3 Catheter-Based Techniques for Valve Interventions

two leaflets of the mitral valve. MitraClip is currently recommended for the treatment of chronic primary mitral regurgitation in inoperable symptomatic patients.¹⁹ Its selective use in acute ischemic mitral regurgitation has been successful.²⁰

AORTIC REGURGITATION

Etiology

Chronic aortic regurgitation is most often due to a congenital bicuspid valve, rheumatic valve disease, or aortic root dilation. There are numerous causes of aortic root dilation, including hypertension, cystic medial necrosis, Marfan syndrome, and a bicuspid aortic valve.²¹ The most common causes of acute aortic regurgitation are endocarditis, rupture of a congenital fenestration, blunt trauma, and acute aortic dissection.¹ Endocarditis results in aortic regurgitation by the destruction of the valve leaflet tissue, with a high percentage of cases also having paravalvular abscess formation. Aortic dissection results in acute aortic regurgitation either due to the enlargement of the aortic annulus or extension of dissection into the valve region, resulting in a flail aortic valve leaflet.

Clinical Presentation

The acute backflow of blood from the aorta to the left ventricle in diastole results in an acute elevation in LV end-diastolic pressure, with consequent pulmonary edema. Because there is no time for compensatory LV dilation, forward cardiac output falls abruptly owing to the regurgitant flow across the valve in diastole, so patients with acute aortic regurgitation may also be in cardiogenic shock. Decreased coronary perfusion pressure results in diffuse subendocardial ischemia, further impairing ventricular function.

Diagnosis

The clinical diagnosis of acute aortic regurgitation differs markedly from that of chronic aortic regurgitation (Fig. 85-4). In contrast to the high-pitched diastolic decrescendo murmur of chronic aortic regurgitation, there is a "to-and-fro" murmur across the aortic valve that many clinicians fail to recognize as an indication of aortic regurgitation. The pulse pressure is narrow due to the low forward stroke volume, and peripheral signs of aortic regurgitation are not seen. As with acute mitral regurgitation, physical examination findings are often subtle, so a high index of suspicion and prompt echocardiography are needed to make this diagnosis.

Acute aortic regurgitation should be considered in patients with signs or symptoms of endocarditis, with a personal or family history of aortic root disease, and with a presentation consistent with acute aortic dissection.²²

Echocardiography allows the imaging of the aortic valve and root and determination of the severity of aortic regurgitation based on a

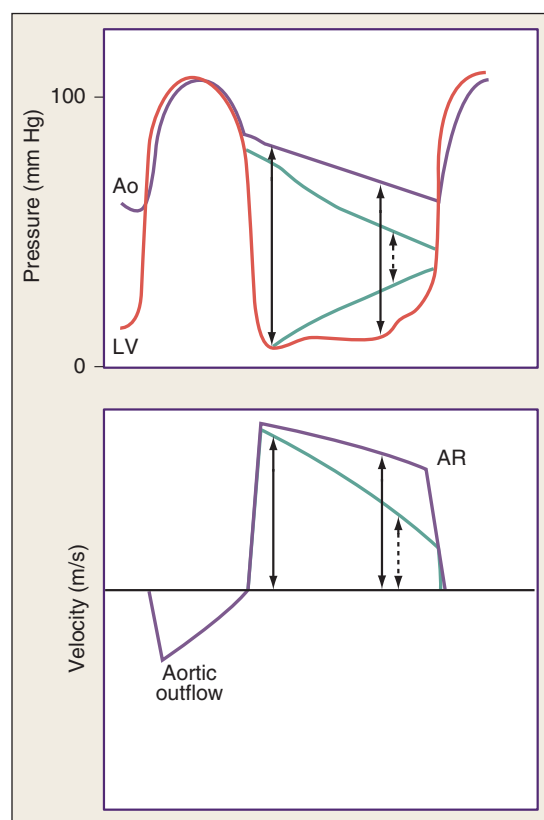

FIGURE 85-4 ■ Left ventricular (LV) and central aortic (Ao) pressures and corresponding Doppler velocity curves are shown for chronic (purple lines) and acute (green lines) aortic regurgitation. The shape of velocity curve is related to the instantaneous pressure differences across the valve over the cardiac cycle, as stated in the Bernoulli equation. With acute aortic regurgitation (AR), aortic pressures fall more rapidly and ventricular diastolic pressure rises more rapidly, resulting in a steeper deceleration slope on the Doppler curve. (From Otto CM. Textbook of clinical echocardiography. 5th ed. Philadelphia: Saunders; 2013, p. 316.)

combination of two-dimensional (2D) imaging and pulsed, continuous-wave, and color Doppler modalities (Figs. 85-5 and 85-6).²³ The continuous-wave Doppler curve shows a steep diastolic slope corresponding to the rapid equalization of diastolic pressure in the aorta and left ventricle. With severe acute regurgitation, there is no pressure gradient at end diastole, so cuff diastolic blood pressure is equal to LV end-diastolic pressure. Echocardiography also allows the accurate assessment of LV size and systolic function. When the differential diagnosis includes aortic dissection, transthoracic echocardiography is inadequate to exclude this possibility. Instead, TEE or computed tomography (CT) images should be obtained.

Management

Acute aortic regurgitation is a surgical emergency.¹ Preoperative management is supportive, with ventilatory support and invasive hemodynamic monitoring. While the diagnosis is being made, therapy may include the use of diuretics, inotropic agents, and nitroprusside or other vasodilators in an attempt to stabilize hemodynamics.^{1,9} However, an IABP is contraindicated, as inflation of the balloon in the descending thoracic aorta in diastole will increase the amount of backflow across the aortic valve.

If acute aortic regurgitation is due to aortic dissection, acute surgical intervention is needed. The surgical approach may be the

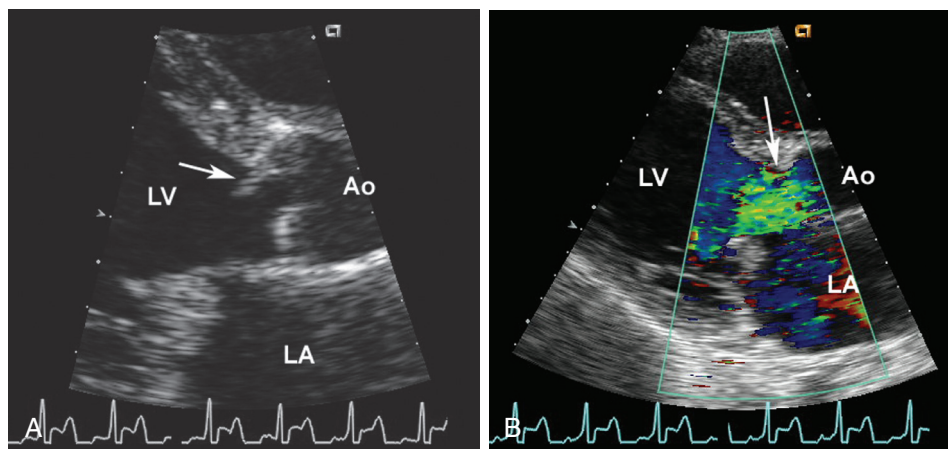

FIGURE 85-5 ■ Endocarditis resulting in acute severe aortic regurgitation. In a long-axis view of the aortic valve (**A**), a flail aortic valve leaflet is seen (arrow), with the leaflet (arrow) prolapsing into the left ventricular (LV) outflow tract in diastole. Color-flow Doppler imaging (**B**) in the same view shows a broad jet of diastolic flow filling the outflow tract, consistent with severe regurgitation. Ao, aorta; LA, left atrium; LV, left ventricle.

FIGURE 85-6 ■ Same patient as Fig. 85-5. Continuous-wave Doppler recording of flow across the aortic valve shows an increased antegrade velocity in systole (S) consistent with a high transaortic stroke volume. In diastole (D), a dense signal of retrograde flow is seen, with a steep deceleration slope (arrow) consistent with rapid equalization of pressures between the aorta and left ventricle in diastole from acute regurgitation.

replacement of the ascending aorta and valve with a combined prosthetic valve and fabric tube. When the valve leaflets are normal, some centers will preserve the native valve by the resuspension of the leaflets in the prosthetic conduit (called the *David procedure*). Beta blockers should be avoided when acute aortic regurgitation complicates an aortic dissection. A reduction in heart rate leads to increased diastolic retrograde filling of the left ventricle, raising LV end-diastolic pressures and compromising hemodynamics.

When acute aortic regurgitation is due to endocarditis, surgical options include a mechanical valve, a heterograft tissue valve such as a porcine aortic valve or bovine pericardial valve, or a cryopreserved homograft aorta valve. Rarely, the patient may undergo valve repair if there is a simple perforation with adjacent normal leaflet tissue.

■ MITRAL STENOSIS

Etiology and Clinical Presentation

Mitral stenosis is almost always due to rheumatic disease, with only rare cases of calcific mitral stenosis seen in the elderly. Rheumatic mitral stenosis is a slowly progressive disease with an insidious decline in exercise tolerance and symptom onset over many years.²⁴ However, in an asymptomatic patient with compensated moderate or severe mitral stenosis, acute decompensation can occur in the setting of increased systemic hemodynamic demands. Because mitral stenosis is more common in women (80% of cases) and occurs during the reproductive years, the most common emergency presentation of mitral stenosis is a pregnant woman with heart failure. Many of these patients are unaware of the underlying valve disease and are initially diagnosed during pregnancy. The clinical presentation may also be due to or exacerbated by the onset of atrial fibrillation.

A large atrial myxoma may mimic the clinical presentation of mitral stenosis, presenting with acute hemodynamic compromise due to the obstruction of the mitral valve orifice by the tumor mass.

Diagnosis

The apical diastolic rumble and opening snap of mitral stenosis is challenging to appreciate even in a quiet room with optimal patient positioning and is frequently inaudible in the ICU setting. However, the diagnosis is easily made by transthoracic echocardiography, with the mitral leaflet showing the characteristic findings of rheumatic disease: commissural fusion, chordal shortening and fusion, and restriction of the diastolic opening of the leaflets (Fig. 85-7).²⁵ The mitral valve area can be quantitated by 2D or three-dimensional planimetry or the Doppler pressure half-time method, with severe stenosis defined as a valve area of less than 1.5 cm² (Fig. 85-8). Transthoracic echocardiography also provides information on LV size and systolic function, left atrial size, pulmonary pressure, and any associated valve lesions. If evaluation for left atrial thrombus is needed, TTE has a sensitivity of only 60% compared to that of nearly 100% of the transesophageal approach.

Management

Most patients with mitral stenosis and acute decompensation can be managed conservatively with the treatment of the superimposed

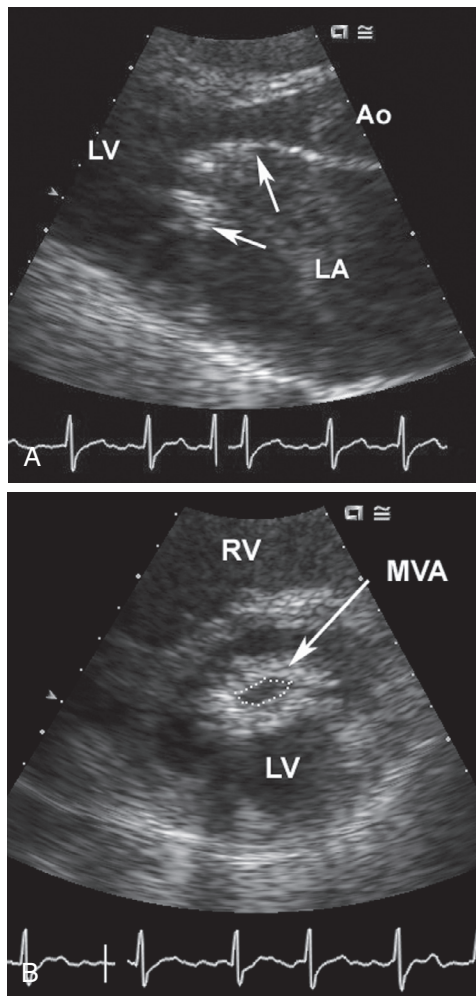

FIGURE 85-7 ■ In a patient with mitral stenosis, the long-axis view (A) demonstrates the classic findings of the diastolic doming of leaflets (arrows) due to commissural fusion, with thickening predominantly at the leaflet tips. In the short-axis view (B), the restricted mitral orifice with fusion of the commissures is visualized, providing accurate measurement of the valve area by direct planimetry. In this case, the valve area of 0.7 cm^2 indicates severe valve obstruction. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

illness.⁹ Efforts should be directed toward decreasing overall metabolic demand and increasing oxygen delivery by controlling fever, maintaining a normal hemoglobin level, and providing supplemental oxygen. If atrial fibrillation is present, rate control is essential, preferably with conversion back to sinus rhythm. Even when sinus rhythm is present, beta blockers may improve ventricular diastolic filling by prolonging the duration of diastole as the heart rate is decreased.²⁶ Invasive hemodynamic monitoring and ventilatory support may be needed when severe heart failure is present.

In patients who do not respond to conservative therapy, emergency intervention should be considered. The optimal intervention is percutaneous balloon mitral valvotomy (PBMV), which typically results in an increase in mitral valve area to more than 1.5 cm^2 (Fig. 85-9).^{27,28} PBMV can be safely performed even during pregnancy.²⁹⁻³¹ Patients with a left atrial thrombus, coexisting moderate to severe mitral regurgitation, or heavily calcified and deformed mitral valves are not candidates for PBMV; in these patients, surgical mitral valve replacement may be needed.

FIGURE 85-8 ■ Same patient as Fig. 85-7. The apical four-chamber view (A) shows severe left atrial enlargement due to mitral obstruction, with thickened valve leaflets (arrow). Haziness in the left atrium is due to the stasis of blood flow, with spontaneous contrast on echocardiography. (B) Continuous-wave Doppler recording of flow across mitral valve shows increased velocity corresponding to transvalvular pressure gradient. Pressure half-time (T1/2) can be used to accurately calculate mitral valve area (0.7 cm^2).

■ AORTIC STENOSIS

Etiology and Clinical Presentation

Valvular aortic stenosis in adults is most often due to the calcification of a normal trileaflet or congenital bicuspid valve (Fig. 85-10A). Rheumatic aortic stenosis is less common and is invariably accompanied by mitral valve involvement. In younger adults, congenital aortic stenosis may be encountered; some of these patients have restenosis after prior commissurotomy in childhood.

Like mitral stenosis, aortic valve stenosis is a chronic, slowly progressive disease that presents acutely only in patients who have not been receiving regular medical care.³²⁻³⁴ As in mitral stenosis, acute decompensation may occur with a superimposed systemic condition. Young women with congenital aortic stenosis may present with angina or heart failure during pregnancy. In older adults, asymptomatic patients with moderate to severe valve obstruction may present with heart failure in the setting of pneumonia, anemia, or other conditions with increased metabolic demands.

Diagnosis

Classic physical examination findings for aortic stenosis include a delayed and decreased carotid upstroke, a narrow pulse pressure, a single second heart sound (S_2), and a systolic ejection murmur at the

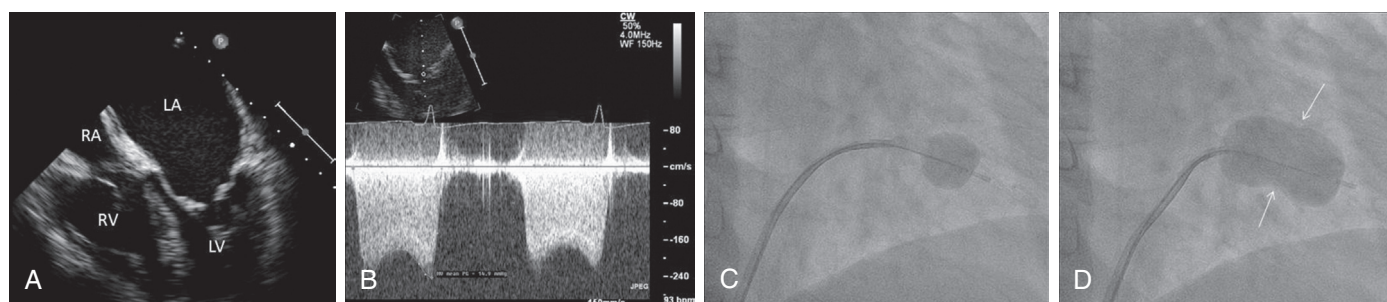

FIGURE 85-9 ■ This 48-year-old female underwent percutaneous balloon mitral valvotomy (PBMV) due to severe symptomatic rheumatic mitral stenosis and acute pulmonary edema. The transesophageal echocardiogram four-chamber view demonstrates restricted diastolic mitral valve opening with hockey-stick deformation and severely enlarged left atrium (**A**). Continuous wave Doppler prior to PBMV measures a severely elevated mean gradient of 15 mm Hg (**B**). Fluoroscopic images show the use of an Inoue balloon distally inflated across the mitral valve via a transseptal catheter (**C**). The initial distal inflation stabilizes the position of the balloon, allowing for full inflation to split the mitral valve commissures, a waist (white arrows) in the balloon is seen from the resistance of the mitral valve (**D**). Successful PBMV reduced the mean gradient to 6 mm Hg and relieved the patient's symptoms. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

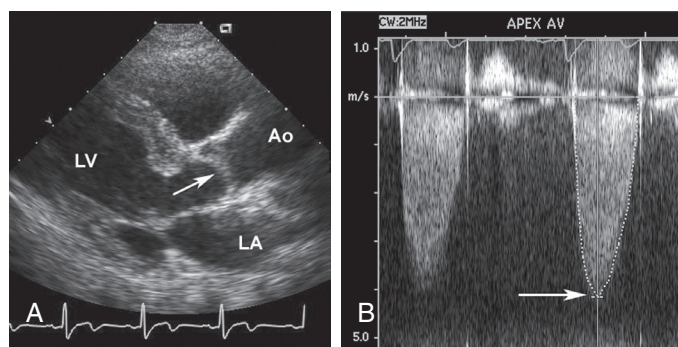

FIGURE 85-10 ■ **A**, In this 26-year-old pregnant woman with a loud systolic murmur, the long-axis view shows doming of the aortic valve in systole (arrow). Short-axis images confirmed a unicuspid aortic valve. **B**, Continuous-wave Doppler examination of the aortic valve demonstrates a high-velocity signal consistent with severe aortic stenosis. The maximum velocity of 4.2 m/sec corresponds to a maximum transaortic pressure gradient of 69 mm Hg and a mean gradient of 41 mm Hg. Valve area, calculated by the continuity equation, was 0.8 cm². Ao, aorta; LA, left atrium; LV, left ventricle.

aortic region that radiates to the carotids. However, while a grade 4 murmur (palpable thrill) with a single S₂ and diminished carotids is specific for severe stenosis, these findings are very insensitive for the diagnosis.³⁵ In particular, when a patient is decompensated, the murmur may be soft, and carotid upstrokes may be altered by coexisting vascular disease or loading conditions.

Echocardiography provides the reliable evaluation of aortic stenosis severity based on the maximum velocity through the narrowed orifice and valve area, calculated with the continuity equation (Fig. 85-10B). Disease severity is a continuum, and velocities may be relatively low despite severe stenosis when stroke volume is reduced. In general, stenosis can be graded as severe (valve area < 1.0 cm² or jet velocity > 4 m/sec), moderate (valve area, 1.0–1.5 cm² or jet velocity, 3–4 m/sec), or mild (valve area > 1.5 cm² or jet velocity < 3 m/sec). Echocardiography also allows the evaluation of ventricular systolic and diastolic function and any associated valve disease.²³

Management

As with mitral stenosis, most patients with decompensated aortic stenosis can be managed conservatively by (1) treating the underlying disease process that led to decompensation and (2) restoring the patient's normal loading conditions. However, in patients who have denied symptoms or have not been receiving medical care, the first presentation of severe aortic stenosis may be syncope or pulmonary edema. In these patients, aortic stenosis is the cause of decompensation, as evidenced by very severe valve obstruction, often with a low ejection fraction. Treatment is urgent aortic valve replacement. The cautious use of nitroprusside may improve hemodynamics prior to valve replacement in severe decompensated aortic stenosis, if the mean arterial pressure is above 60 mm Hg,^{36,37} and some patients can be managed by careful diuresis. However, in unstable patients who are surgical candidates, it is more prudent to proceed promptly to valve replacement. For prohibitive and high-risk surgical patients, transcatheter aortic valve implantation can be performed in experienced centers.^{38,39} If aortic valve replacement is temporarily contraindicated, primarily due to an active infection, balloon aortic valvuloplasty can be used.⁴⁰

RIGHT-SIDED VALVE DISEASE

Pulmonic valve disease is almost always congenital in origin, with a chronic disease course. Tricuspid valve stenosis is rare and usually accompanies rheumatic mitral valve disease. Tricuspid valve endocarditis often results in acute severe regurgitation; pulmonic valve endocarditis is rare. Cases of acute traumatic disruption of the tricuspid valve with blunt chest trauma have been described, although myocardial contusion or thoracic aorta disruption is more common.^{41,42} Acute severe tricuspid regurgitation results in a low forward cardiac output and signs of an elevated right atrial pressure.

PROSTHETIC VALVES

Mechanical Valves

Prosthetic mechanical heart valves are very durable, with complications most often due to valve thrombosis or paravalvular regurgitation.⁴³ Valve thrombosis occurs in the setting of inadequate anticoagulation and may result in functional valve stenosis if movement of the valve occluder is restricted or valve regurgitation if the clot

FIGURE 85-11 ■ Transesophageal echocardiogram of a thrombosed bileaflet mechanical mitral valve in a 43-year-old female who stopped anticoagulation for a dental procedure with inadequate bridging. In systole (**A**), the bright occluder can be seen in a closed position, causing reverberation artifact into the left ventricle (LV). During diastole (**B**), there is a minimal opening of the occluder (*white arrow*) from the acute thrombus. Color-flow Doppler (**C**) shows flow primarily through only one side of the valve, while there is only a very narrow jet at the site of the stuck leaflet. Continuous-wave Doppler (**D**) estimated a severely elevated mean gradient of 24 mm Hg, and the patient required emergent surgical valve replacement with a bioprosthesis.

prevents full closure of the valve. The clinical presentation of valve thrombosis is similar to that of native valve stenosis or regurgitation. Echocardiography provides key information on the presence and severity of valve dysfunction.⁴⁴ TEE is especially important with mitral prosthetic valves (**Fig. 85-11**); the valve itself blocks ultrasound penetration from a transthoracic approach.

The treatment of prosthetic valve thrombosis is controversial. When only a small thrombus and mild hemodynamic compromise are present, conservative therapy with full-dose intravenous anticoagulation for several days may be adequate. With severe hemodynamic compromise, surgical intervention with repeat valve replacement may be necessary, although operative mortality is reported to be high, ranging from 17% to 40%.⁶ Systemic thrombolytic therapy can restore valve function in about 80% of patients but is associated with death in 20%, systemic embolism due to fragmentation of the valve thrombosis in 16%, and the need for emergency surgery in 20%.⁶ The duration of thrombolytic therapy is based on the resolution of the Doppler echocardiographic evidence of the resolution of thrombus and valve dysfunction. Current guidelines recommend emergency operation for left-sided valve thrombosis and severe symptoms or a large clot burden, except in patients with an excessively high surgical risk. Fibrinolytic therapy is reasonable for right-sided valve thrombosis, left-sided thrombosis with mild symptoms of recent onset or a small clot burden, and patients who are not surgical candidates.^{6,45,46}

Paravalvular regurgitation early after valve replacement may be related to suture dehiscence at a site of annular calcification. Paravalvular regurgitation may be associated with hemolytic anemia, which can be treated conservatively if mild but may require reoperation if severe recurrent anemia is present. The new onset of paravalvular regurgitation should prompt careful evaluation for endocarditis (see Chapter 86). Paravalvular regurgitation has been successfully treated with the percutaneous techniques in high-risk surgical candidates with refractory heart failure and hemolytic anemia (**Fig. 85-12**).⁴⁷

Tissue Valves

Tissue valves are subject to the degeneration of the leaflets, with superimposed calcification that may result in stenosis or regurgitation. Usually, this is a slowly progressive process with presentation 10 to 15 years after valve implantation.⁴⁸ As with native valve disease, acute

FIGURE 85-12 ■ Severe paravalvular leak in a 72-year-old male with a history of multiple mitral valve (MV) replacements due to previous endocarditis presenting with symptomatic heart failure and hemolytic anemia. Two-dimensional transesophageal color Doppler (**A**) shows eccentric regurgitation around the closed prosthetic MV occluder (*) during systole. Three-dimensional echocardiography (**B**) assists with paravalvular closure of the defect using an Amplatzer plug (*black arrow*). A second plug is required in this case and can be seen being deployed via a transseptal catheter (*white arrow*) during diastole with an open MV occluder. IAS, interatrial septum; LA, left atrium; LV, left ventricle; RVOT, right ventricular outflow tract.

decompensation may occur in patients with chronic prosthetic valve dysfunction if there is a superimposed hemodynamic stress.

Acute regurgitation of a tissue valve can result from endocarditis or a leaflet tear due to tissue degeneration. Tears in the valve leaflet typically occur adjacent to an area of calcification secondary to the increased stress on the normal leaflet tissue. As with mechanical valves, both transthoracic and transesophageal imaging are needed for the full evaluation of suspected prosthetic tissue valve dysfunction. Treatment is similar to that for native valves, with medical stabilization followed by surgery for repeat valve replacement. However, many patients are at a very high surgical risk due to advanced age, comorbidities, and repeated sternotomy; in these patients, investigational transcatheter techniques for “valve-in-valve” replacement may be performed at experienced centers.⁴⁹

KEY POINTS

Acute Mitral Regurgitation

1. Causes include endocarditis, mitral prolapse, and acute myocardial infarction
2. Presents with pulmonary edema
3. Murmur may be soft or absent.
4. Prompt echocardiography is essential.
5. Pulmonary wedge v-wave is not always seen.
6. Intraaortic balloon pump improves hemodynamics.
7. Definitive treatment is mitral valve surgery, but transcatheter approaches may be considered in selected patients.

Acute Aortic Regurgitation

1. Causes include endocarditis and aortic dissection
2. Diastolic murmur may be soft.
3. Prompt echocardiography is essential.
4. Treatment is emergency aortic valve replacement surgery.

Mitral Stenosis

1. Rheumatic mitral stenosis typically occurs in young women.
2. May present during pregnancy
3. Echocardiography is diagnostic.

4. Acute decompensation can be treated medically.
5. Percutaneous balloon mitral commissurotomy is the optimal intervention.

Aortic Stenosis

1. Aortic stenosis is common in the elderly.
2. Decompensation occurs with increased hemodynamic demand.
3. Physical examination shows a systolic murmur.
4. Echocardiography is diagnostic.
5. Conservative management for decompensation is appropriate.
6. Severe symptomatic disease requires surgical or transcatheter aortic valve replacement.

Prosthetic Valves

1. Mechanical valves are at a risk of valve thrombosis.
2. Management of prosthetic valve thrombosis is controversial.
3. Tissue valves undergo degeneration 10 to 15 years after implantation.
4. Presentation and management of acute regurgitation is similar to native valve disease.

ANNOTATED REFERENCES

Detailed summary of the literature on acute valve regurgitation, clinical presentation, diagnostic approach, and management. Surgical considerations in the decision for valve repair versus replacement are reviewed. References to earlier publications can be found here.

Prendergast BD, Tornos P. Surgery for infective endocarditis: who and when? *Circulation* 2010;121:1141-52.

Review paper that summarizes the literature on the timing of surgery for infective endocarditis and provides a practical approach for patient management.

Lalani T, Cabell CH, Benjamin DK, et al. Analysis of the impact of early surgery on in-hospital mortality of native valve endocarditis: use of propensity score and instrumental variable methods to adjust for treatment-selection bias. *Circulation* 2010;121:1005-13.

In this prospective study of 1552 patients with native valve endocarditis, the 46% who underwent early surgery were compared to the 54% who were treated medically. Overall survival was significantly better with early surgery, with an estimated absolute risk reduction of 11%. Propensity score sub-

group analysis identified patients most likely to benefit from early surgery as those with paravalvular complications, systemic embolization, infection with Staphylococcus aureus, and stroke.

Chandrasekhar Y, Westaby S, Narula J. Mitral stenosis. *Lancet* 2009;374:1271-83.

Review of mitral stenosis including epidemiology and pathology, diagnosis, clinical course, and management. The management of mitral stenosis during pregnancy and the role of percutaneous mitral valvotomy are emphasized.

Sun JC, Davidson MJ, Lamy A, Eikelboom JW. Antithrombotic management of patients with prosthetic heart valves: current evidence and future trends. *Lancet* 2009;374:565-76.

This review of antithrombotic therapy for prosthetic valves covers preventive anticoagulation and management of thrombotic complications. For obstructive valve thrombosis, the authors recommend thrombolytic therapy and echocardiographic monitoring, with surgery reserved for patients with contraindications to thrombolysis or those who do not respond to thrombolytic therapy. Smaller (<5 mm) nonobstructive thrombi can usually be managed with standard anticoagulation alone.

Infectious endocarditis is associated with a myriad of complications, both cardiac and extracardiac, that may require intensive care unit (ICU) admission. Local progression of the infection causes destruction of valve cusps or leaflets and chordae and may extend to peri- and paravalvular structures. Hemodynamic deterioration leads to secondary organ failure. Finally, embolization of infected tissues may damage vital organs and cause peripheral abscesses. Intensivists are often confronted with complex treatment decisions, such as the indication for and timing of cardiac surgery and the management of hemodynamic and neurologic complications. Therefore, treatment of patients with complicated infectious endocarditis requires close cooperation between intensivists, infectious disease specialists, cardiologists, and cardiac surgeons. This chapter focuses on the changing epidemiology and progress made during the past 2 decades in the diagnosis and management of complicated infectious endocarditis.

■ PATHOPHYSIOLOGY

Infectious endocarditis is a microbial infection of the endocardial surface of the heart. The process is initiated by bloodborne microorganisms that adhere directly to the endothelium or by nonbacterial thrombotic endocarditis. The most important factors facilitating nonbacterial thrombotic endocarditis are organic valvular lesions, with associated perturbation of blood flow, and prosthetic valves. Circulating microorganisms can adhere to microscopic lesions, which explains why some patients with infectious endocarditis have no previously known valvular abnormality.¹

In simple infectious endocarditis, infection is limited to the valve cusps or leaflets and chordae and consists of vegetations (Fig. 86-1) that are formed by pathogens, platelets, fibrin, and inflammatory cells. In advanced infectious endocarditis, deep tissue invasion results in the destruction or invasion of valvular and perivalvular structures. The infection may spread as cellulitis, with the formation of an abscess or pseudoaneurysm that can rupture into another heart chamber or even the pericardium.

In prosthetic valve endocarditis (PVE), lesions may differ according to the type of prosthesis. With biological prostheses or homografts, the infection may be limited to the cusps, whereas with mechanical prostheses, involvement of the sewing ring and valve annulus is the rule. Bacterial adherence to the prosthesis results from a complex relationship among the biomaterial, plasma proteins (e.g., fibronectin, laminin, thrombospondin, fibrinogen), and bacterial adhesion proteins. Staphylococci express numerous surface factors: clumping factors A and B, which promote bacterial adhesion to fibrinogen and fibrin, and fibronectin-binding proteins A and B, which permit adhesion to fibronectin.² In addition, once staphylococci have escaped the microbicidal effects of platelet peptides, they can bind to the platelet surface by a series of pathogenetic steps including direct binding to the platelet surface, upregulation of platelet surface receptors for fibrinogen, and interaction between specific bacterial proteins and platelet surface receptors. Surface charge modifications are associated with increased in vitro resistance profiles of *Staphylococcus aureus* to a number of endogenous cationic antimicrobial peptides, such as α -defensins.^{3,4}

■ INCIDENCE AND CLASSIFICATION

The incidence of infective endocarditis ranges from 3 to 10 episodes/100,000 person-years, varying from one country to another.

This may reflect methodological differences between surveys rather than true variations.⁵ The overall annual incidence of infectious endocarditis in Europe and the United States is between 15 and 60 cases per million. In a study conducted in France, the crude annual incidence of infectious endocarditis was 30 (95% confidence interval [CI], 27 to 33) per million inhabitants.¹ Infectious endocarditis can be classified into three groups that differ markedly in terms of incidence, clinical presentation, microbiological features, and outcome: left-sided native valve, right-sided native valve, and PVE.

Left-sided native valve infectious endocarditis traditionally occurs in patients with underlying heart disease, but it may also affect patients with no known valvular disease, especially when endocarditis is caused by highly virulent bacteria such as *S. aureus* or *Streptococcus pneumoniae*. Most infections are community acquired, but nosocomial cases are becoming more common.

Right-sided native valve infectious endocarditis is usually associated with intravenous (IV) drug use and still accounts for 10% of all infectious endocarditis episodes.⁶ Nosocomial cases are frequently a consequence of catheter-related infections. In most cases of pacemaker and implantable cardioverter-defibrillator infectious endocarditis, vegetations are located only on leads, but tricuspid valve involvement may also occur.⁷

Prosthetic valve endocarditis occurs in 1% to 6% of patients with a valve prosthesis, with an incidence of 0.3% to 1.2% per patient-year.⁴ It accounted for 21% of the 2781 patients with definite infective endocarditis in the International Collaboration on Endocarditis–Prospective Cohort Study⁶ (ICE-PCS). Early PVE is classically defined as occurring within 1 year of surgery and late PVE as occurring beyond 1 year because of significant differences between the microbiological profiles observed before (usually nosocomial origin) and after this time point (predominance of community-acquired pathogens).⁸ However, a recent large prospective multicenter international registry found that 37% of all PVE was associated with nosocomial infections or nonnosocomial healthcare-associated infections in outpatients with extensive healthcare contact.⁹

■ DEMOGRAPHICS AND ETIOLOGIC PROFILES

Classic and Changing Patient Characteristics

The demographic characteristics of patients who develop infectious endocarditis have changed over the past few decades. Today, patients tend to be older, and their underlying diseases have changed.^{10,11} In ICE-PCS, 38% of all definite infectious endocarditis occurred in patients older than 65 years.¹¹ In developing countries, rheumatic heart disease remains the most frequent underlying cardiac condition predisposing patients to infectious endocarditis. In contrast, nonrheumatic heart abnormalities, including mitral valve prolapse, aortic valve calcification, aortic bicuspid valve, and hypertrophic obstructive cardiomyopathy, are the main risk factors in the United States and Western Europe. For patients with mitral valve prolapse, risk factors include mitral regurgitation and thickened mitral leaflets. However, results of a 1-year survey of infectious endocarditis in France showed a significantly lower incidence of known underlying heart disease between 1991 and 1999. Nowadays, congenital heart diseases are rarely involved, except bicuspid aortic valve. Other conditions, including diabetes mellitus, long-term hemodialysis, and immunosuppression,

FIGURE 86-1 ■ Vegetations on a native mitral valve in a patient with streptococcal endocarditis.

are associated with a higher incidence of infectious endocarditis. At Duke University Medical Center, rates of hemodialysis dependence and immunosuppression among 329 patients with infectious endocarditis rose significantly between 1993 and 1999.¹² Moreover, a recent study showed that more than one-third of cases of native valve endocarditis in non-injection drug users involve contact with healthcare. Such episodes of endocarditis may be nosocomial if they occur in a patient hospitalized for more than 48 hours before the onset of signs or symptoms consistent with infective endocarditis. A higher proportion of nonnosocomial healthcare-associated endocarditis is now observed in patients with extensive out-of-hospital contact with healthcare interventions or systems (e.g., wound care, receipt of hemodialysis or IV chemotherapy, residence in a nursing home or long-term care facility).¹³

Causative Organisms

Overall Distribution

Most Frequently Isolated Pathogens. Streptococci are traditionally the most common causative agent of infectious endocarditis, but the results of the ICE-PCS showed that streptococci had fallen to second place behind staphylococci as the leading cause.⁶ However, this apparent temporal shift from predominantly streptococcal to predominantly staphylococcal infective endocarditis may be partly due to recruitment/referral bias in specialized centers, since this trend is not evident in population-based epidemiologic surveys of infective endocarditis.¹⁴ *Streptococcus* species (mainly *Streptococcus mitis*, *Streptococcus sanguis*, and *Streptococcus mutans*), which abound in the mouth and nasopharynx, are associated with dental procedures and diseases. Poor dental hygiene and minor or unrecognized periodontal disease may be the source of *Streptococcus viridans* infectious endocarditis. *Streptococcus gallolyticus* (previously *S. bovis*) may be involved in valve infections of dental or buccal origin. In addition, the association of *S. gallolyticus* with carcinoma or other lesions of the colon (e.g., diverticulitis, polyps) is well known. Beta-hemolytic streptococci (groups A, B, C, and G) and *Streptococcus milleri* are isolated from 6% of patients with infectious endocarditis,¹ with the predominant species being group B. The majority of nonpregnant patients with group B streptococcal infectious endocarditis have an underlying condition, such as diabetes mellitus, breast cancer, decubitus ulcer, or cirrhosis.¹⁵

Enterococci, mainly *Enterococcus faecalis* and *Enterococcus faecium*, account for only 10% of cases of infectious endocarditis.⁶ These pathogens affect older patients, as demonstrated by a description of 93 episodes of enterococcal infectious endocarditis occurring in patients with a mean age of 74 years.¹⁶ The portals of entry are the gastrointestinal and urogenital tracts through a lesion or a procedure (e.g., injection sclerotherapy of esophageal varices, transurethral prostate resection, urethral dilatation) resulting in transient bacteremia, in which case the infection is healthcare associated.

Staphylococcus aureus is now implicated in approximately 30% of all cases of left-sided native valve infectious endocarditis⁶ and in 23%

of PVE.⁹ It is the most common cause of healthcare-associated infections.¹⁵ *S. aureus* is also the causative agent in most acute infections, with about half of patients having no previously known heart disease. A clinically identifiable focus of infection (e.g., carbuncle, cellulitis, bursitis, ulcer, burn, osteomyelitis) may be present. However, in 50% to 60% of cases, no obvious portal of entry is detected, although the skin is probably the source in many of them. The relationship between *S. aureus* nasal carriage and infection has been established in specific subsets of patients, especially in IV drug users and patients with diabetes mellitus or on hemodialysis.¹² Methicillin-resistant strains are isolated in healthcare-associated endocarditis, although rare cases of community-acquired methicillin-resistant endocarditis have been reported.

Coagulase-negative staphylococci (CoNS), in a recent international study, were found to cause 16% of 537 cases of definite noninjecting drug use-associated PVE. Nearly 50% of patients with CoNS PVE presented between 60 days and 365 days after valve implantation. Methicillin resistance was present in 68% of CoNS strains.¹⁷ CoNS are also a well-documented, albeit rather rare, cause of native valve infective endocarditis. Most patients have documented valvular abnormalities, especially mitral valve prolapse. A substantial subset of CoNS infective endocarditis has been identified as being due to *Staphylococcus lugdunensis*, which causes destructive cardiac lesions; its differentiation from other CoNS species in the laboratory may be difficult.

Overall, staphylococci, streptococci, and enterococci account for more than 80% of microorganisms responsible for infective endocarditis.

Infrequent Pathogens: Enterobacteriaceae and HACEK Group.

Despite the high frequency of Enterobacteriaceae bacteremia leading to severe sepsis or septic shock, infectious endocarditis caused by these pathogens is extremely uncommon, probably because gram-negative bacilli adhere less avidly to the endothelium than do gram-positive cocci. Most cases of native valve infective endocarditis develop in patients with severe comorbidities, including cirrhosis or immunosuppression.¹⁸ Gram-negative bacilli are usually encountered in early and late PVE, but they account for only 2% of cases. Bacteria of the HACEK group (fastidious organisms) originate from the oropharyngeal or urogenital flora and include *Haemophilus aphrophilus* or *paraphrophilus* (H), *Actinobacillus actinomycetemcomitans* (A), *Cardiobacterium hominis* (C), *Eikenella corrodens* (E), and *Kingella* species (K). These HACEK pathogens are implicated in 2% of cases of infectious endocarditis on either native or prosthetic valves.⁶

Streptococcus pneumoniae infectious endocarditis occurs more commonly in alcoholics, but other patients, such as those with diabetes, malignancy, or chronic obstructive pulmonary disease, may be affected as well. Approximately 65% to 80% of patients have no known predisposing cardiopathy. The primary infection focus is the lungs, and meningitis is present in 40% to 60% of cases.¹⁹

Fungi are a rare cause of infective endocarditis, being isolated in 2% of all cases but in 4% of those patients with prosthetic valve infection. Although injection drug use was traditionally an important risk factor, a recent study showed that patients with *Candida* infective endocarditis were more likely to have a prosthetic valve, short-term indwelling catheters, and healthcare-associated infections.²⁰ Other fungi, such as *Aspergillus* spp., are even less frequently encountered. Fungi are frequently responsible for mural endocarditis.

Patients with Negative Blood Cultures. Five main points should be emphasized: (1) *Abiotrophia* spp. (previously classified as nutritionally variant streptococci) are the main cause of culture-negative infective endocarditis in patients who have recently received antibiotics. (2) Only 5% to 7% of patients who have not recently taken antibiotics have negative blood cultures. Polymerase chain reaction (PCR; of samples from blood, excised vegetation, or systemic emboli) can be used to identify the causative organism, such as *Bartonella* spp., *Tropheryma whippelii*, or *Coxiella burnetii*, as well as streptococci or other pathogens not isolated from blood cultures.²¹ (3) Serologic tests are useful to diagnose infectious endocarditis caused by those organisms or by *Brucella* and *Legionella* species. (4) HACEK organisms may

require prolonged incubation and subculturing. (5) *Candida* (but not *Aspergillus*) spp. are usually isolated from routine blood cultures, but in some cases, fungi are recovered only from excised vegetations or peripheral emboli.

Specific Microbiological Characteristics of Infectious Endocarditis in ICU Patients

The microbiological characteristics of infectious endocarditis in patients who require ICU admission differ from those in the overall population. Analysis of a large series of infectious endocarditis patients hospitalized in two medical ICUs in a Parisian teaching hospital between 1994 and 2001 showed that *S. aureus* was the leading pathogen responsible for left-sided native valve and PVE²² (Table 86-1). Those figures were confirmed by an Austrian study of 33 ICU patients with infectious endocarditis: *S. aureus* was isolated from 36% of patients, versus 15% *S. viridans* and 12% enterococci.²³ In a French multicenter study, *S. aureus* accounted for 46% of 198 critically ill patients with definite endocarditis according to Duke criteria (see later discussion).²⁴ Clearly these findings are largely explained by *S. aureus* causing valve destruction, septic shock, and emboli to vital organs, such as the brain.

CLINICAL CHARACTERISTICS AND DIAGNOSIS

In 1994, a new set of diagnostic criteria, known as the *Duke criteria*, were proposed for the diagnosis of infectious endocarditis. It included two major and six minor criteria. Modifications of these criteria were proposed in 2000 to take into account transesophageal echocardiography findings and to consider all *S. aureus* bacteremias and positive Q fever serology as major criteria.²⁵

Clinical Characteristics

In ICU patients, the clinical presentation of infectious endocarditis often includes extracardiac manifestations or findings associated with cardiac complications. Patients are generally referred to the ICU for cardiogenic or septic shock, pulmonary edema caused by valvular or prosthetic dysfunction, neurologic events, acute renal failure, or respiratory failure in the setting of pulmonary emboli complicating right-sided infectious endocarditis. Two salient features, usually

associated with high-grade fever, strongly suggest the diagnosis of infectious endocarditis: (1) a heart murmur (most commonly preexisting) or a prosthetic valve and (2) petechiae on the skin (especially the extremities; Fig. 86-2) and conjunctivae. A typical ICU candidate has an acute febrile and toxic illness with a heart murmur, petechiae, and meningeal signs. Cerebrospinal fluid examination reveals pleocytosis and gram-positive cocci. Blood cultures yield *S. aureus*, and echocardiography confirms left-sided infectious endocarditis. In patients with catheter-related bacteremia, the diagnosis of infective endocarditis may be suggested by persistent positive blood cultures 3 to 5 days after the onset of antimicrobial treatment and removal of the catheter.

Echocardiography

Echocardiography has the following objectives: (1) to detect vegetations and determine their size, (2) to diagnose paravalvular extension of the infection, (3) to evaluate myocardial function, (4) to detect pericardial effusion, and (5) if cardiac surgery is being considered, to measure the valve ring to choose the appropriate prosthetic valve for replacement. Transthoracic echocardiography is rapidly obtained and noninvasive, but its overall sensitivity is only 40% to 65%. False-negative results are obtained when the examination is inadequate (especially in patients with obesity or chronic obstructive pulmonary disease) or when vegetations are less than 5 mm. Transesophageal echocardiography associated with color Doppler techniques is more invasive, but its sensitivity for detecting vegetations is 90% to 100%.⁵ Transesophageal echocardiography is particularly useful in patients with suspected valve perforation or extension of perivalvular infectious endocarditis and in those with PVE. Its sensitivity and specificity for the detection of cardiac abscess are 80% and 95%, respectively. This technique is necessary for all patients undergoing valve surgery and may be repeated at close intervals to help the physician decide when to operate. However, transesophageal echocardiography should be used cautiously in nonintubated critically ill patients with respiratory failure. Follow-up echocardiography to monitor complications and response to treatment is mandatory.⁵

COMPLICATIONS

Cardiac complications and hemodynamic failure, central nervous system (CNS) complications, and acute renal failure are the leading causes of ICU admission for patients with infectious endocarditis. Other complications are not addressed in detail.

Cardiac Complications and Hemodynamic Failure

Congestive heart failure (CHF) is usually caused by infection-induced valvular damage or prosthesis dysfunction. CHF is observed in 50% to 60% of cases overall and is more frequently associated with aortic disease than with mitral disease. CHF caused by aortic failure may require urgent valve replacement. Perivalvular extension of infectious endocarditis is frequently associated with CHF, and spread into the septum may lead to heart block. Erosion of a mycotic aneurysm of the sinus of Valsalva can cause hemopericardium and tamponade or can create fistulas to the right or left ventricle. Myocardial infarction due to coronary artery embolization is a rare event. Hemodynamic failure can also be caused by septic shock, especially during the bacteremic phase of *S. aureus* infectious endocarditis.²² All these complications may require the administration of positive inotropes or vasoconstrictors and the use of mechanical ventilation before valve replacement.

Neurologic Complications

CNS complications of infectious endocarditis occur frequently. They may be the first or predominant manifestation of the disease and can

FIGURE 86-2 ■ Typical purpuric lesions in a patient with *Staphylococcus aureus* mitral valve endocarditis.

arise through several mechanisms. CNS complications are a leading cause of death due to infectious endocarditis, and their specific management may be complex.

Frequency, Microbiology, and Timing

In most series, CNS involvement during the course of infectious endocarditis occurs in 20% to 40% of cases. Among 1329 episodes of infectious endocarditis from seven series described between 1985 and 1993, 437 (33%) were accompanied by CNS manifestations.²⁶ In a Finnish teaching hospital, 55 of 218 infectious endocarditis (25%) episodes were associated with neurologic complications.²⁷ However, two other studies reported lower rates: in France, strokes occurred in 17% of 264 infectious endocarditis cases caused by staphylococci or streptococci,¹ and in the United States, among 513 episodes of complicated, left-sided, native valve infectious endocarditis, focal neurologic signs or altered mental status were observed in 18% and 16% of cases, respectively.¹⁰ Experience from the large, contemporary ICE-PCS reported a similar (17%) incidence of strokes.⁶ The use of sensitive methods of detection, such as magnetic resonance imaging (MRI), indicates that silent cerebral complications are frequent. Among 60 patients who experienced episodes of left-sided infective endocarditis, 35% had a symptomatic neurologic event, while silent cerebral complications were detected in another 30%.²⁸ In a recently published study involving 127 patients with definite endocarditis who underwent systematic MRI, cerebral lesions were detected in 106 patients, most being asymptomatic.²⁹ Not surprisingly, the incidence of symptomatic neurologic complications is much higher in the subset of patients with infective endocarditis requiring admission to the ICU. A multicenter study showed a 55% incidence of symptomatic neurologic events among 198 critically ill patients with left-sided endocarditis.²⁴ Neurologic complications are a hallmark of left-sided abnormalities of either native or prosthetic valves. When neurologic complication rates were assessed as a function of the causative agent, the frequency of CNS involvement was two to three times higher with *S. aureus* than with other pathogens.²⁷

Most neurologic complications are already evident at the time of hospitalization or develop within a few days. The probability of developing these complications decreases rapidly once antimicrobial therapy has been started. In the ICE-PCS, the crude incidence of stroke in patients receiving appropriate antimicrobial therapy was 4.82/1000 patient-days in the first week of therapy and fell to 1.71/1000 patient-days in the second week. This rate continued to decline with further

FIGURE 86-3 ■ T2-weighted magnetic resonance imaging sequence performed at the acute phase of aortic valve *Staphylococcus aureus* endocarditis, showing multiple ischemic cerebral lesions.

therapy.³⁰ Moreover, recurrent neurologic events, although possible even late, are uncommon.

Pathogenesis and Distribution

Neurologic complications of infectious endocarditis can arise through various mechanisms, but the major mechanism is cerebral embolization. Cerebral emboli (Fig. 86-3) result from dislodgment or fragmentation of cardiac vegetations, followed by vessel occlusion; this results in various degrees of ischemia and infarction, depending on the vessels and collateral blood flow. Occlusion of cerebral arteries, with either stroke or transient ischemic attack, accounts for 40% to 50% of CNS complications of infectious endocarditis.²⁶⁻²⁷ Cerebral hemorrhage may be the consequence of different mechanisms, each of which accounts for one-third of bleeding complications: rupture of an intracranial aneurysm; septic erosion of the arterial wall, without a well-delineated aneurysm (acute necrotizing arteritis); or hemorrhagic transformation of ischemic brain infarcts, especially in anticoagulated patients. Overall, intracranial hemorrhage represents 10% of CNS complications. Brain hemorrhage is more frequent during the bacteremic phase of *S. aureus* infectious endocarditis and is more likely with severe thrombocytopenia and anticoagulant therapy.²² A case-control study using diffusion-weighted MRI (Fig. 86-4) reported that cerebral microbleeds were observed in 57% of patients with infective endocarditis, compared to 15% of control subjects.³¹ Meningitis, occurring in 5% to 40% of patients with CNS manifestations of infectious endocarditis, can be the consequence of a wide variety of mechanisms. The cerebrospinal fluid may be purulent with positive cultures, clear with moderate pleocytosis, or hemorrhagic. Brain abscesses associated with infectious endocarditis are uncommon; they account for less than 5% of CNS events, but the rate depends on the imaging technique used. In addition, many small abscesses or areas of cerebritis resolve with antibiotics alone. Finally, *toxic encephalopathy*, defined as mental changes or stupor without focal neurologic manifestations and without computed tomography (CT) abnormalities, is often included among the CNS complications of infectious endocarditis. Obviously this manifestation can have different causes, such as subtle cerebral lesions, or it may be present in the setting of severe sepsis.²⁴

Specific Management

Infectious endocarditis occurring in patients receiving anticoagulant therapy poses a difficult problem. In the absence of CNS complications or in patients with nonhemorrhagic neurologic lesions, warfarin should be discontinued and replaced by heparin. However, in the presence of brain hemorrhage, anticoagulant therapy should be

FIGURE 86-4 ■ T2-weighted magnetic resonance imaging sequence performed at the acute phase of definite mitral valve *Staphylococcus aureus* endocarditis, showing multiple cerebral microbleeds (arrows).

temporarily discontinued. CT scanning is essential for the diagnosis and management of CNS events associated with infectious endocarditis. In addition, it may be the only technique available for unstable ICU patients, especially those receiving mechanical ventilation. CT may show intracranial bleeding, ischemic lesions, or a pattern consistent with cerebral abscess. MRI is more sensitive for most lesions and should be performed in hemodynamically stable patients because it can modify clinical management.²⁹ Although conventional four-vessel angiography remains the gold standard for the evaluation of mycotic aneurysms, magnetic resonance angiography is a promising technique. In the absence of randomized trials, which are difficult (if not impossible) to organize, the respective roles of medical, endovascular, and neurosurgical treatment of intracranial aneurysms are not easily assessable. Endovascular treatment (coil embolization) seems to be a reliable and safe technique that should be considered when cerebral mycotic aneurysms are diagnosed.³²

Acute Renal Failure

Acute renal failure occurs in up to 40% of complicated infectious endocarditis cases necessitating ICU admission^{2,23} and may result from several mechanisms. It is often the consequence of cardiogenic or septic shock (with or without multiorgan failure), leading to acute tubular necrosis. Drugs, such as the combination of a glycopeptide and an aminoglycoside, and the use of iodine contrast medium for radiologic investigations may cause further deterioration of renal function. In some patients with streptococcal or staphylococcal infectious endocarditis, acute renal failure is caused by severe glomerulonephritis. Acute renal failure may require the initiation of dialysis.

Other Complications

Systemic embolism can involve many organs, such as the spleen and kidneys; rarely, the liver or the iliac, mesenteric, or peripheral arteries are involved. Splenic abscesses are caused mainly by *S. aureus* or *S. viridans*. Abdominal CT is the best procedure to detect splenic abscesses, which may require percutaneous drainage or splenectomy. Pulmonary emboli, the hallmark of right-sided endocarditis, may be

responsible for respiratory failure or even acute respiratory distress syndrome, especially in IV drug users with *S. aureus* infectious endocarditis.

MEDICAL AND SURGICAL TREATMENT

In the absence of large prospective randomized studies, which present a considerable challenge, the overall strategy for infectious endocarditis treatment is derived mainly from retrospective series, clinical judgment, and expert recommendations.

Antibiotic Treatment

Certain general principles underlie the current guidelines^{5,33} for infectious endocarditis treatment. In cases of streptococcal infectious endocarditis, determination of the minimal inhibitory concentration of penicillin is necessary to choose the best regimen. Parenteral antibiotics are recommended over oral drugs because of the importance of sustained antibacterial activity, which requires high dosages (e.g., 150 to 200 mg/kg of amoxicillin for streptococcal infectious endocarditis). However, oral antibiotics may be considered for right-sided *S. aureus* infectious endocarditis after a few days of parenteral antibiotics if IV administration is not possible because of poor venous access. In that case, the combination of a fluoroquinolone and rifampin is an acceptable regimen. Many experts recommend using a combination of agents with activities against the cell wall (β -lactams or glycopeptides) plus an aminoglycoside (gentamicin) for most cases of infectious endocarditis, especially complicated cases, such as those occurring in ICU patients. Gentamicin can be administered in one or two daily doses, except for infective endocarditis due to enterococci, for which two doses are recommended. The use and duration of aminoglycosides depend on the pathogen and, for streptococci, their susceptibility to penicillin G and the presence of a prosthesis (Table 86-2). Although a shorter course of aminoglycosides has been proposed for enterococcal infectious endocarditis,¹⁶ no controlled study has confirmed the safety of this strategy. For staphylococcal infectious endocarditis, a triple regimen including rifampin is recommended,³⁴ especially for patients with PVE. Short-term therapy (15 days) was shown to be effective in selected cases of uncomplicated *S. aureus* right-sided infectious endocarditis or left-sided native valve infectious endocarditis due to highly susceptible streptococci. However, most current recommendations emphasize prolonged antibiotic administration (4–6 weeks or even 8 weeks) for *S. aureus* PVE. The results of repeat valve cultures, but not positive gram staining or positive PCR, should be taken into account to decide how long to continue antimicrobial therapy after valve replacement.⁵

The role of new molecules in the treatment of infective endocarditis remains to be evaluated. Daptomycin is a bactericidal lipopeptide that can be used in methicillin-resistant *S. aureus*³⁵ and vancomycin-resistant enterococci infective endocarditis.³⁶

Surgical Management

In recent series,^{6,9} 48% to 50% of patients (up to 75% in specialized medical-surgical centers) undergo valve replacement during the acute phase of infectious endocarditis before the completion of antibiotic treatment.

Indications for and Timing of Cardiac Surgery

Absolute indications are CHF caused by valvular insufficiency, prosthesis obstruction or dehiscence, periannular abscess, or *S. aureus* or fungal PVE. These microorganisms cannot be eradicated without removal of the prosthesis. The development of CHF in the setting of infectious endocarditis generally requires cardiac valve replacement regardless of the number of days on antibiotics. Emergency cardiac surgery is recommended for the following situations: (1) aortic or mitral infective endocarditis with severe acute regurgitation or valve obstruction, causing refractory pulmonary edema or cardiogenic

TABLE 86-2

Antibiotic Treatment of Complicated Infectious Endocarditis as a Function of Valve Type, Pathogen, and Susceptibility

| MICROORGANISM | NATIVE-VALVE INFECTIOUS ENDOCARDITIS | PROSTHETIC-VALVE ENDOCARDITIS |
|---|---|---|
| Penicillin-susceptible streptococci (MIC < 0.125 mg/L) | Penicillin G, amoxicillin, or ceftriaxone for 4 wk* | Penicillin G or amoxicillin for 6 wk + gentamicin for 2 wk* |
| Relatively penicillin-resistant streptococci (MIC ≥ 0.125-2 mg/L) | Penicillin G or amoxicillin for 4 wk + gentamicin for 2 wk* | Penicillin G or amoxicillin for 4-6 wk + gentamicin for 4 wk* |
| Streptococci with penicillin G MIC > 2 mg/L, enterococci, and <i>Abiotrophia</i> spp. | Penicillin G or amoxicillin for 4-6 wk + gentamicin for 4 wk* | Penicillin G or amoxicillin for 6 wk + gentamicin for 6 wk* |
| MSSA | Nafcillin or oxacillin for 4-6 wk + gentamicin for 3-5 days† | Nafcillin or oxacillin + rifampin for ≥6 wk + gentamicin for 2 wk† |
| MRSA | Vancomycin + rifampin for 4-6 wk + gentamicin for 3-5 days | Vancomycin + rifampin for ≥6 wk + gentamicin for 2 wk |
| HACEK organisms | Ceftriaxone or cefotaxime for 4 wk | Ceftriaxone or cefotaxime for 6 wk |
| Enterobacteriaceae | Ceftriaxone or cefotaxime for 4 wk + gentamicin or amikacin for 1 wk‡ | Ceftriaxone or cefotaxime for 6 wk + gentamicin or amikacin for 2 wk‡ |
| <i>Bartonella</i> spp. | Ceftriaxone or doxycycline for 6 wk + gentamicin for 2-3 wk | Ceftriaxone or doxycycline for 6 wk + gentamicin for 2-3 wk |
| <i>Coxiella burnetii</i> | Doxycycline or ofloxacin + hydroxychloroquine for ≥18 mo | Doxycycline or ofloxacin + hydroxychloroquine for ≥18 mo |
| <i>Candida</i> spp. | LF AmB with or without 5-FC or AmB with or without 5-FC or an echinocandin for 2 wk, then fluconazole for susceptible organism in stable patient with negative blood culture results for 4 wk | LF AmB with or without 5-FC or AmB with or without 5-FC or an echinocandin for 2 wk, then fluconazole for susceptible organism in stable patient with negative blood culture results for 4 wk. Lifelong suppressive therapy for prosthetic valve endocarditis is recommended if valve cannot be replaced. |

*Vancomycin or teicoplanin therapy is indicated for patients who are allergic to β -lactam antibiotics. Optimal antimicrobial therapy is not available for high-level aminoglycoside-resistant and vancomycin-resistant enterococci. Eradicating these pathogens requires consultation with an infectious disease specialist or a microbiologist.

†A first-generation cephalosporin is indicated for patients who are allergic to penicillin, except those with immediate-type hypersensitivity reactions to β -lactam antibiotics, who should be treated with a glycopeptide.

‡The results of susceptibility tests might indicate the need to adapt the initial regimen.

5-FC, 5-fluorocytosine; HACEK, *Haemophilus aphrophilus* or *paraphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species; LF AmB, lipid formulation of amphotericin B; MIC, minimal inhibitory concentration; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *S. aureus*.

shock and (2) aortic or mitral infective endocarditis with a fistula into a cardiac chamber or pericardium, causing pulmonary edema or shock.⁵

Relative indications requiring case-by-case evaluation are persistent bacteremia beyond 7 days despite appropriate antibiotic therapy, non-*S. aureus* PVE, and difficult-to-treat organisms, such as *C. burnetii*, *Bartonella* spp., multiresistant enterococci, or *P. aeruginosa*, especially in patients with PVE.

With regard to other potential indications, contraindications, and timing of valve replacement, the following factors should be emphasized. (1) Although the risk of systemic embolization is higher in patients with large vegetations on the mitral valve, vegetation characteristics alone rarely justify valve surgery. The decreasing risk of emboli with time, especially after the first week of effective antibiotic therapy, should be considered when deciding whether to operate.³⁰ (2) In patients with neurologic complications, a conservative approach is to delay cardiac surgery for 2 or 3 weeks after an embolic event and for at least 1 month after cerebral bleeding. However, in the case of CHF, the valve can be replaced within 7 days or less after an embolic infarct, especially when the infarct is of limited size and the patient's good mental status prevails.⁵ (3) In that case, there is a high probability of complete neurologic recovery.³⁷ True contraindications to valve surgery are rare and include uncontrolled septic shock, unhealed sternal wound infection, and severe coagulation disorders.

Coronary angiography is recommended for patients older than 40 years and those with at least one risk factor for coronary artery disease, except when emergency surgery is needed.⁵

Surgical Technique

Surgery includes complete removal of all infected and necrotic tissue, followed by valve reconstruction. In selected cases, good results have

been achieved with conservative mitral valve valvuloplasty. In most patients, valve replacement with a mechanical or biological prosthesis or a homograft is necessary. The use of cryopreserved homografts has been suggested to reduce the risk of persistent or recurrent infection. However, mechanical prostheses and xenografts compare favorably, with improved durability.³⁸

OUTCOME AND PROGNOSTIC FACTORS

The overall in-hospital mortality was 18% in the large, contemporary ICE-PCS.⁶ This figure included all types of infectious endocarditis, however, and warrants refinement according to the different categories of disease. Another recent cohort of 513 patients with complicated left-sided native valve infectious endocarditis had a 6-month mortality rate of 26%.¹⁰ Two studies found mortality rates for PVE of 33% and 22%, respectively.^{9,36} In the ICE-PCS, healthcare-associated native valve endocarditis was associated with higher in-hospital mortality (25%) compared to community-acquired endocarditis (13%).¹³ Survival of ICU patients with infective endocarditis is lower. Among 228 patients with infectious endocarditis referred to the two ICUs in our hospital, the in-hospital mortality rate was 45%.²² It was 42% in a multicenter study involving 198 critically ill patients with infective endocarditis.²⁴

Prognostic factors for survival have been studied by several authors. In most cases, these reflect the site of infectious endocarditis (see earlier discussion), comorbidities, causative agent, and types of complications. CHF, septic shock, neurologic events, *S. aureus* PVE, increasing age, and paravalvular complications are associated with in-hospital mortality in most studies.^{6,10,13,23,24} The hemodynamic status of the patient at the time of valve replacement is the main determinant of perioperative mortality, with a poorer prognosis for patients with

pulmonary edema or impaired left ventricular function.^{3,7} Neurologic events markedly increase the risk of death, which can reach 50% in patients with altered mental status.¹⁰ Among microorganisms, *S. aureus* is associated with higher mortality rates than streptococci for left-sided native valve endocarditis and PVE.^{13,25,26} Finally, mounting evidence shows that for both complicated left-sided native valve infectious endocarditis and *S. aureus* PVE, valve replacement during active endocarditis combined with medical therapy is associated with a better outcome than medical treatment alone.^{6,12,13,39,40} The reoperation rate, mainly for prosthesis dehiscence or new infectious endocarditis, is 2% to 3% per year, and the 5-year survival rate is approximately 80% to 90% for native valve infectious endocarditis and 60% for PVE. A

scoring system taking into account mental status, comorbidity, CHF, microbiology, and use of surgical treatment in left-sided native valve infectious endocarditis was recently published.⁴¹

CONCLUSION

Despite advances in both diagnosis and treatment, infectious endocarditis still carries high morbidity and mortality rates, especially for patients requiring ICU admission. Improvement of outcomes requires a multidisciplinary approach to optimize medical treatment and decision making concerning valve surgery.

Hypertension is a common problem, and population data suggest its incidence is increasing globally. One billion individuals worldwide now have hypertension.¹ Nearly one in three U.S. adults have hypertension. Compared to two-thirds in the past decade, currently half of these individuals don't have their blood pressure under control. One-third of those in whom it is not controlled are unaware of their diagnosis.^{2,3} The exact risk of hypertensive crisis is not clear, but most authors estimate it to be less than 1%. The incidence may have decreased with widespread use of antihypertensive therapy.^{4,5}

Hypertensive emergency is defined as an elevated blood pressure associated with evidence of acute end-organ damage. With acute damage to vital organs such as the kidney, heart, and brain, there is a significant risk of morbidity in hours without therapeutic intervention. Both the absolute level of blood pressure and the time course of the elevation determine the development of an emergency. In general with hypertensive emergency, the diastolic blood pressure is above 120 mm Hg. However, in children, gravid females, and previously normotensive individuals, hypertensive emergencies may occur with relatively minor increases in blood pressure. It is very important to identify this syndrome early to prevent end-organ damage and institute appropriate therapy as soon as the diagnosis is made. Malignant hypertension is a specific syndrome in which a markedly elevated blood pressure is associated with hypertensive neuroretinopathy.

Individuals with *hypertensive urgency* have an elevated blood pressure (systolic blood pressure often > 180 and diastolic pressure often > 115 mm Hg) without evidence of acute end-organ damage. Hypertensive urgency may be associated with chronic, stable complications such as stable angina, previous myocardial infarction, chronic congestive heart failure, chronic renal failure, previous transient ischemic attacks, or previous cerebrovascular accident with no threat of an acute insult. The focus of this chapter is on both types of hypertensive crises, with the emphasis on hypertensive emergency.

PATHOPHYSIOLOGY OF HYPERTENSIVE EMERGENCY

The precise pathophysiology of hypertensive emergency is unknown. An abrupt increase in blood pressure is one of the initiating events in the transition from simple hypertension or normotension to hypertensive emergency. The product of cardiac output and peripheral vascular resistance determines blood pressure. The initial blood pressure increase is likely secondary to an increase in vascular resistance. Considerable evidence suggests that mechanical stress in the arteriolar wall leads to disruption of endothelial integrity.⁶ With disruption of vascular integrity, diffuse microvascular lesions develop.^{7,8} Fibrinoid necrosis of the arterioles is seen in vulnerable organs and is considered the histologic hallmark of hypertensive emergency.^{7,8} It is unclear whether hypertension alone causes the development to hypertensive emergency or whether other factors are necessary. For example, increases in peripheral vascular resistance result in part from activation of the renin-angiotensin-aldosterone system. Evidence suggests angiotensin II may directly injure the vascular wall by activation of genes for proinflammatory cytokines (e.g., interleukin 6) and also of nuclear factor κ B.^{9,10} Other vascular-toxic influences may contribute to increased peripheral vascular resistance, including hyperviscosity, immunologic factors, and other hormones including catecholamines, vasopressin, and endothelin.¹¹⁻¹³ The end result of these changes is a

significant increase in peripheral vascular resistance, with ischemia of heart, brain, and kidneys.

In considering hypertensive emergencies and their treatment, the impact of blood pressure on cerebrovascular physiology is important. For example, hypertensive encephalopathy is a distinct clinical syndrome that occurs when rapidly rising central perfusion pressures exceed the ability of the central nervous system (CNS) to autoregulate. *Autoregulation* of cerebral blood flow (CBF) refers to the ability of the brain to maintain a constant CBF as the cerebral perfusion pressure (CPP) varies between 60 to 150 mm Hg. In the setting of chronic hypertension, the range of autoregulation is increased to a range of 80 to 160 mm Hg. Autoregulation of CBF is a function of CPP (derived from the mean arterial pressure [MAP] minus the venous pressure) and cerebral vascular resistance (CVR), according to the following equation:

$$CBF = CPP / CVR$$

Under normal physiologic conditions, the backflow in the cerebral venous system or venous pressure is near zero, and the arterial pressure determines the CPP. With acute brain injury, as seen with subarachnoid hemorrhage, stroke, and intracranial hemorrhage, the ability of the brain to autoregulate and maintain CBF is impaired. Inability to autoregulate CBF is also seen in hypertensive emergency when the MAP is greater than 140 mm Hg.

DIAGNOSIS OF HYPERTENSIVE EMERGENCIES

Medical History, Physical Examination, and Laboratory Evaluation

From 40% to 50% of hypertensive emergencies arise in patients with preexisting hypertension without identifiable secondary causes.^{14,15} Essential hypertension is the underlying disorder in the majority of African American individuals.¹⁶⁻¹⁸ In contrast, from 50% to 60% of white patients with malignant hypertension have an identifiable cause (Box 87-1). Renovascular hypertension secondary to either fibromuscular dysplasia or atherosclerosis is not uncommon. Hypertensive emergency can occur in individuals with no hypertensive history, as in preeclampsia, pheochromocytoma, drug withdrawal, and acute glomerulonephritis. A medication history, including over-the-counter medications and illegal drug use, should be ascertained from every patient. Malignant hypertension is a unique clinical and pathologic syndrome where increases in blood pressure and target-organ damage are caused by changes in the vasculature characterized by fibrinoid necrosis and a proliferative endarteritis. Risk factors associated with the development of malignant hypertension include age between 30 and 50 years,¹⁹ male gender,⁶ African American background,¹⁵ and smoking (increases the risk by 2.5- to 5-fold).²¹

The clinical presentation of hypertensive emergency may include headache that is generally located occipitally or anteriorly, with a steady quality. Other symptoms include visual complaints (scotoma, diplopia, hemianopsia, blindness), neurologic symptoms (focal deficits, stroke, transient ischemic attacks, seizures, confusion, somnolence), ischemic chest pain, renal symptoms (nocturia, polyuria, hematuria), back pain (aortic aneurysm), and gastrointestinal complaints (nausea,

 Antihypertensive withdrawal
 Cocaine intoxication, sympathomimetic overdose

vomiting). Weight loss occurs as the high levels of circulating renin and angiotensin induce a diuresis.²² These patients often present with intravascular volume depletion, which has strong implications for treatment.

The blood pressure is measured in both arms with the patient lying and standing. Pathologic processes such as atherosclerosis, Monckeberg's medial calcification, and metastatic calcification as experienced in end-stage renal disease (ESRD), cause stiffening of the vascular wall, which can prevent vessel compression by external compression with a blood pressure cuff. This results in an artificial and at times extreme increase in the systolic and diastolic blood pressure, or "pseudohypertension." Clues to pseudohypertension include a markedly elevated blood pressure in an individual without evidence of end-organ damage. The diagnosis is suggested by a palpable radial artery despite proximal compression with a sphygmomanometer (Osler's maneuver).²³

A dilated funduscopic examination should be performed on all individuals. Arteriolar thickening reflects chronic hypertension and is manifested by increased light reflex, vascular tortuosity, and arteriovenous nicking where the arterioles cross the venules. These changes have

 Drug withdrawal

no prognostic significance with regard to hypertensive emergency. However, as hypertension increases in severity, there are additional findings caused by the breakdown of the blood-retina barrier, leading to retinal hemorrhage and leakage of lipids, causing hard exudates or cotton-wool spots as a result of nerve ischemia and swelling of the optic nerve with papilledema.²⁴

A complete cardiovascular examination should include a careful evaluation for evidence of left ventricular hypertrophy and heart failure and peripheral pulse examination for absence or delay suggestive of aortic dissection. Examination of the abdomen should include evaluation for enlarged kidneys as seen with polycystic kidney disease as well as for evidence of aortic aneurysm. Last, a careful neurologic examination should be done to rule out any evidence of a cerebral vascular accident. Alterations in mental status may indicate a stroke or hypertensive encephalopathy. The initial laboratory evaluation should include a serum sodium, chloride, potassium, bicarbonate, creatinine and blood urea nitrogen, complete blood count (with a peripheral smear to identify schistocytes), prothrombin time, activated partial thromboplastin time, serum and urine toxicology screen, pregnancy test when appropriate, an electrocardiogram, and a urinalysis. Evidence of intravascular hemolysis is common and may make it difficult to differentiate hypertensive emergency from primary vasculitis with secondary hypertension.^{25,26} The renin-angiotensin-aldosterone axis is markedly activated, as evidenced by hypokalemia and metabolic alkalosis.^{4,27} The blood urea nitrogen and creatinine are often elevated. The urinalysis may show small amounts of proteinuria as well as hematuria with occasional erythrocyte casts.⁶ Marked increases in proteinuria suggest a primary glomerular process such as glomerulonephritis as the etiology of the elevated blood pressure.

If hypertensive encephalopathy is suspected, magnetic resonance imaging (MRI) of the brain should be performed. Edema seen posteriorly, particularly in the parieto-occipital regions (a finding called *posterior leukoencephalopathy*) and rarely in the brainstem are the manifestations of hypertensive encephalopathy.^{28,29} It is important to consider and eliminate other conditions with a similar clinical presentation (Box 87-2). Several important diagnostic considerations help exclude other causes of altered mental status: (1) symptoms of generalized brain dysfunction tend to develop over time (12-24 hours) with hypertensive encephalopathy, as compared with acutely in ischemic stroke or cerebral hemorrhage; (2) focal neurologic findings are unusual with hypertensive encephalopathy unless there is an associated bleed; (3) papilledema is almost always noted with hypertensive encephalopathy and if absent should raise suspicion of another etiology; and (4) in comparison with an acute CNS bleed, mental status with hypertensive encephalopathy improves within 24 to 48 hours of treatment.

TREATMENT OF HYPERTENSIVE EMERGENCY

Patients with hypertensive emergency are best treated parenterally with intensive care monitoring by arterial cannulation or automated blood pressure cuff measurement. In general, the need to lower the blood

pressure and the rate at which this should occur is dictated by the clinical setting. Excessive falls in pressure should be avoided, given the potential for resulting in renal, cerebral, and coronary ischemia.

In most but not all settings, blood pressure can be reduced acutely by 20% to 25% within minutes to hours.⁴ Although the autoregulatory range of CBF is reset upward in chronic hypertension, the lower limit of the autoregulation remains approximately 25% below the resting MAP in patients with both normotension and chronic hypertension.³⁰ When the arterial blood pressure falls below this lower limit, CBF progressively decreases and symptoms of low CBF, including nausea, yawning, hyperventilation, clamminess, and syncope, develop. To protect cerebral function, after an initial reduction of blood pressure by 20% within the first hour, blood pressure is further reduced over the next 2 to 6 hours to the 160/110 range as long as the patient remains stable.⁴ Assuming continued stability, the blood pressure may then be decreased to 140/90 mm Hg over the next 24 to 48 hours.⁴ With these decreases in blood pressure, CBF autoregulation is usually maintained. There are several clinical settings where additional issues and alternative approaches to reducing blood pressure should be considered. In ischemic stroke, immediate reduction of blood pressure is usually not indicated except when the blood pressure is over 220/120 or the patient requires thrombolytic therapy. Recent data indicate that acute blood pressure reduction is of no benefit (CATIS trial) or even harmful (SCAST trial).^{31,32} In intracerebral hemorrhage, acute lowering of systolic blood pressure to 140 mm Hg is recommended based on weak evidence. Results of the recent INTERACT2 study support this recommendation.³³ In acute aortic dissection, if the patient tolerates, a rapid blood pressure reduction in 15 to 30 minutes to a systolic blood pressure under 100 mm Hg is clinically warranted. Finally, in previously normotensive subjects with abrupt increases in BP and those with active unstable angina or congestive heart failure with pulmonary edema,

Exceptions to rapid blood pressure reduction may include older patients with carotid stenosis, since these individuals are particularly susceptible to CNS hypoperfusion. Significant reduction of blood pressure in the setting of ischemic stroke may not be beneficial (discussed later). Overall, blood pressure management in patients with stroke or intracranial bleeding is controversial, since the loss of CBF autoregulation and the presence of brain edema require high systemic pressures to provide adequate cerebral perfusion.

SPECIFIC TREATMENT RECOMMENDATIONS FOR HYPERTENSIVE EMERGENCY BASED ON ETIOLOGY

General Comments on Medications Used to Treat Hypertensive Emergency

The classes of parenteral antihypertensive agents available to treat hypertensive emergency include direct vasodilators (sodium nitroprusside, nitroglycerin), α - and β -adrenergic blockers (labetalol), α -adrenergic blockade (phenolamine), angiotensin-converting enzyme (ACE) inhibitors (enalaprilat), calcium channel blockers (nicardipine and clevidipine), and dopamine agonists (fenoldopam). Some of the advantages and disadvantages of these medications are detailed in Table 87-1. There is no consensus on the most effective antihypertensive medications in the setting of a CNS insult and no large randomized trials demonstrating the superiority of a given agent. Rather, the choice of antihypertensive therapy should be individualized to the patient and clinical setting. Most authors now caution against the use of nitroprusside in the setting of increases in intracranial pressure (ICP). Vasodilators increase blood volume and therefore have the potential to increase the ICP. Animal and human studies in the setting of a normal ICP show no effect of nitroprusside on ICP.²⁵⁻²⁷ However, in studies on animals and humans with preexisting increased ICP, nitroprusside further increased the ICP, likely reflecting vasodilatation on the background of decreased cranial compliance.³⁴⁻³⁸ When sodium nitroprusside is

contraindicated, other treatment options include labetalol and nicardipine. Fenoldopam, which is an agonist of the vasodilator dopamine-1 receptor, shares with nitroprusside a rapid onset and short duration of action. In addition, in contrast to nitroprusside, fenoldopam increases renal blood flow, induces natriuresis, and produces no toxic metabolites.³⁹⁻⁴³

Malignant Hypertension

As noted above, malignant hypertension is specific syndrome characterized by markedly elevated pressures in conjunction with hypertensive neuroretinopathy. Funduscopic examination often reveals flame-shaped hemorrhages, cotton-wool spots, or papilledema. Malignant hypertension is also associated with nephropathy, encephalopathy, microangiopathic hemolytic anemia, and cardiac ischemia. Untreated malignant hypertension is a rapidly fatal disorder, with a mortality of more than 90% within 1 year, as reported in a classic series by Kincaid-Smith.⁷ In this series, deaths were due to renal failure (19%), congestive heart failure (13%), renal failure plus congestive heart failure (48%), stroke (20%), and myocardial infarction (1%).

Aggressive therapy to prevent progressive ischemic injury in malignant hypertension is critical. Nitroprusside had been the preferred agent; however, due to the concerns related to increased ICP, cyanide toxicity in the setting of anemia or liver disease, thiocyanate toxicity in the setting of renal failure, and the availability of the newer agents, its utility has decreased over the years. A number of parenteral agents including fenoldopam and nicardipine have been used as successful alternatives to nitroprusside. If nitroprusside is used, thiocyanate levels should be monitored and the duration of therapy kept to less than 72 hours whenever possible. Fenoldopam has no toxic metabolites and may protect renal function.³⁹⁻⁴³ Premature discontinuation of parenteral therapy may cause rebound hypertension. Oral therapy is usually started after the pressure has been stabilized on parenteral therapy, and the latter is then slowly weaned.

Renal failure is common with malignant hypertension, and, in a vicious cycle, the renal failure exacerbates the hypertension. Aggressive treatment can arrest and reverse renal damage. Since the arteriolopathy of malignant hypertension includes fixed anatomic lesions, initial lowering of blood pressure may worsen renal function. Dialysis may be required in patients presenting with a creatinine greater than 4.5 mg/dL.⁴⁴ In the majority of patients, renal function begins to improve after 2 weeks of therapy. Of the patients who require dialysis, 50% will regain sufficient function to discontinue dialysis.⁴⁵ Recovery of renal function is predicted when the combined length of both kidneys is 20.2 cm or more but is felt to be unlikely when the length is 14.2 or less.⁴⁶ The mean time to recovery is approximately 2 to 3 months, but recovery after up to 26 months has been reported.⁴⁷ In patients with malignant hypertension secondary to glomerulonephritis, eventual deterioration to ESRD may occur despite blood pressure control.⁴⁸ In contrast, renal function tends to remain well preserved in patients without underlying glomerulonephritis if the blood pressure is well controlled.

Hypertensive Encephalopathy

In hypertensive encephalopathy, the MAP exceeds the limits of autoregulation, and brain edema develops from extravasation of plasma proteins. If hypertensive encephalopathy is untreated, coma and death may follow.⁴⁹ The challenge of hypertensive encephalopathy is appropriate lowering of blood pressure in the setting of CNS ischemia and edema. The hallmark of hypertensive encephalopathy is improvement within 12 to 24 hours of adequate blood pressure reduction. The MAP should be cautiously reduced by no more than 15% over 2 to 3 hours. Neurologic complications have been reported from reductions in MAP of 40% or more.⁵⁰

Hypertensive encephalopathy is one of the medical conditions believed to cause reversible posterior leukoencephalopathy, a condition that results from reversible vasogenic subcortical edema without

TABLE 87-1 Treatment of Hypertensive Crisis: Intravenous Medications

| DRUG NAME AND MECHANISM OF ACTION | INDICATIONS/ADVANTAGES/DOSE | DISADVANTAGES/ADVERSE EFFECTS/METABOLISM CAUTIONS |
|---|--|--|
| SODIUM NITROPRUSSIDE Nitric oxide compound; vasodilation of arteriolar and venous smooth muscle Increases cardiac output by decreasing afterload | Useful in most hypertensive emergencies Onset of action immediate, duration of action 1-2 min Dose: 0.25 µg/kg/min Maximum dose: 8-10 µg/kg/min | Contraindicated in high-output cardiac failure, congenital optic atrophy. Anemia and liver disease at risk of cyanide toxicity: acidosis, tachycardia, change in mental status, almond smell on breath. Risk of thiocyanate toxicity with renal disease: psychosis, hyperreflexia, seizure, tinnitus. Cautious use with increased intracranial pressure. Do not use maximum dose for more than 10 minutes. Crosses the placenta. |
| NITROGLYCERIN Directly interacts with nitrate receptors on vascular smooth muscle Primarily dilates venous bed Decreases preload | Use with symptoms of cardiac ischemia, perioperative hypertension in cardiac surgery Initial dose: 5 µg/min Maximum dose: 100 µg/min | Contraindicated in angle-closure glaucoma, increased intracranial pressure. Blood pressure decreased secondary to decreased preload, cardiac output—avoid when cerebral or renal perfusion compromised. Caution with right ventricular infarct. |
| LABETALOL β- and α-Adrenergic blockade α:β-Blocking ratio is 1:7 | Onset of action 2-5 min, duration 3-6 hours Bolus 20 mg, then 20-80 mg every 10 min for maximum dose 300 mg Infuse at 0.5-2 mg/min | Avoid in bronchospasm, bradycardia, congestive heart failure, greater than first-degree heart block, second/third trimester pregnancy. Use caution with hepatic dysfunction, inhalational anesthetics (myocardial depression). Enters breast milk. |
| ESMOLOL Cardioselective β1-adrenergic blocking agent | Use with aortic dissection Use during intubation, intraoperative, and postoperative hypertension Onset of action 60 seconds, duration 10-20 min 200-500 µg/kg/min for 4 min, then infuse 50-300 µg/kg/min | See labetalol. Not dependent on renal or hepatic function for metabolism (metabolized by hydrolysis in red blood cells). |
| FENOLDOPAM Postsynaptic dopamine-1 agonist; decreases peripheral vascular resistance; 10 times more potent than dopamine as vasodilator | May be advantageous in kidney disease, increases renal blood flow, increases sodium excretion, no toxic metabolites Initial dose: 0.1 µg/kg/min, with titration every 15 min No bolus | Contraindicated in glaucoma (may increase intraocular pressure) or allergy to sulfites; hypotension, especially with concurrent β-blocker. Check serum potassium every 6 hours. Concurrent acetaminophen may significantly increase blood levels. Dose-related tachycardia. |
| HYDRALAZINE Primarily dilates arteriolar vasculature | Primarily used in pregnancy/eclampsia Dose: 10 mg every 20-130 min; maximum dose 20 mg Decreases blood pressure in 10-20 min Duration of action 2-4 h | Reflex tachycardia; give β-blocker concurrently. May exacerbate angina. Half-life 3 hours, affects blood pressure for 100 hours. Depends on hepatic acetylation for inactivation. |
| PHEHTOLAMINE α-Adrenergic blockade | Used primarily to treat hypertension from excessive catecholamine excess (e.g., pheochromocytoma) Dose: 5-15 mg Onset of action 1-2 min, duration 3-10 min | β-blockade is generally added to control tachycardia or arrhythmias. As in all catecholamine excess states, β-blockers should never be given first, as the loss of β-adrenergically mediated vasodilatation will leave α-adrenergically mediated vasoconstriction unopposed and result in increased pressure. |
| NICARDIPINE Dihydropyridine calcium channel blocker; inhibits transmembrane influx of calcium ions into cardiac and smooth muscle | Onset of action 10-20 min, duration 1-4 h Initial dose: 5 mg/h to maximum of 15 mg/h | Avoid with congestive heart failure, cardiac ischemia. Adverse effects include tachycardia, flushing, headache. |
| CLEVIDIPINE Short-acting dihydropyridine calcium channel antagonist ¹⁰¹ | Initial dose: 1 mg/h; can be increased to 21 mg/h | Reduces blood pressure without affecting cardiac filling pressures or causing reflex tachycardia |
| ENALAPRILAT Angiotensin-converting enzyme inhibitor | Onset of action 15-20 min, duration 12-24 h Dose: 1.25-5 mg every 6 h | Response not predictable, with high renin states may see acute hypotension. Hyperkalemia in setting of reduced glomerular filtration rate. Avoid in pregnancy. |
| TRIMETHAPHAN Nondepolarizing ganglionic blocking agent; competes with acetylcholine for postsynaptic receptors | Used in aortic dissection Dose: 0.5-5 mg/min | Does not increase cardiac output. No inotropic cardiac effect. Disadvantages include parasympathetic blockade, resulting in paralytic ileus and bladder atony and development of tachyphylaxis after 24-96 hours of use. |

infarction.^{28,29} This syndrome is characterized by headache, decreased alertness, changes in behavior including confusion and diminished speech, seizures, and alterations in visual perceptions. It is rapidly reversible with lowering of the blood pressure.^{28,29} An MRI examination shows characteristic findings including white matter edema in the posterior cerebral hemispheres.²⁸

There is a growing literature supporting a shared pathologic process between hypertensive encephalopathy and eclampsia. Both clinical

syndromes have the same clinical features and imaging findings. Eclampsia during pregnancy, as well as postpartum eclampsia, has also been associated with reversible posterior leukoencephalopathy.^{28,29}

In previously normotensive patients, including those with eclampsia, blood pressure should be normalized. If the mental status worsens with treatment, the pressure should be allowed to increase until neurologic symptoms resolve and then be reduced to within the normal range over several days to allow restoration of autoregulation.

Ischemic Cerebral Infarction

When the CPP decreases below the level of autoregulation, ischemia develops. In response, there may be a marked elevation in arterial blood pressure to maintain perfusion, which tends to spontaneously return to baseline 24 to 48 hours after the acute event. Thus, treatment of acutely increased blood pressure may not be required. Following ischemic cerebrovascular accident, it is also important to consider other causes that may contribute to an increase in blood pressure, including a full bladder, nausea, pain, preexisting hypertension, hypoxia, or increased ICP. Often times, simply calming the patient, treating pain, and relieving a full bladder may reduce the blood pressure.

Data from animal studies show that in the area surrounding the ischemic infarct, there are “neurons at risk” that rely on collateral circulation to maintain perfusion.⁵¹ These neurons are nonfunctional but not dead, a phenomenon referred to as *ischemic penumbra*, and they can potentially be rescued by reperfusion.⁵² The degree to which this occurs in humans is not known. In addition, in acute stroke, autoregulation is impaired, and CBF is therefore not preserved in a predictable manner. As a result of these changes, acute reductions in blood pressure could potentially increase the area of infarct, resulting in severe clinical consequences.

Comprehensive guidelines for the treatment of stroke recommend that patients determined to be candidates for administration of intravenous recombinant tissue plasminogen activator, the blood pressure must be reduced if the systolic blood pressure is >185 mm Hg or the diastolic blood pressure is >110 mm Hg, and the patient must be carefully monitored before, during, and after administration of this compound. Thrombolytic therapy is contraindicated if the blood pressure is >185/100 mm Hg.⁵³

Questions remain as to how to manage individuals with ischemic stroke who are not candidates for thrombolysis. There are no good data from randomized controlled trials to guide blood pressure management. A prospective observational study analyzing the impact of blood pressure lowering in the setting of ischemic stroke in 1092 patients suggested an improved outcome at 3 months with modest reductions in systolic blood pressure between 10 and 27 mm Hg. However, the authors noted that the benefit of blood pressure reduction waned with age. If the systolic pressure was lowered by more than 27 mm Hg, the odds ratio for a poor outcome at 3 months increased more than 5-fold at age 70 to 76 years, nearly 10-fold for 76 to 80 years, and nearly 15-fold in patients older than 80 years.⁵⁴ Moreover, recently published randomized controlled studies, where patients were enrolled as long as 30 to 48 hours after stroke onset, do not show any significant difference in mortality and functional outcome with aggressive hypertension treatment.^{31,32} In the absence of any definitive data, the current recommendation is that if there is no indication for acute lowering of the blood pressure (e.g., acute ischemic damage to vital organs such as cardiac ischemia or aortic dissection), then the threshold for treatment should be a systolic blood pressure over 220 mm Hg or a diastolic blood pressure over 120 mm Hg, with the aim to lower the blood pressure 15% to 25% over the first 24 hours in the acute phase of ischemic stroke.⁵³

Subarachnoid Hemorrhage

Approximately 10% of cerebrovascular accidents are due to subarachnoid hemorrhage, which remains a devastating entity with a mortality rate of 50% to 60% at 30 days and a 50% dependency rate in survivors.⁵⁵ Subarachnoid hemorrhage increases ICP and decreases cerebral perfusion, causing global ischemia. Complications include an intracerebral hemorrhage or the development of hydrocephalus. Management of these patients is significantly different from those with ischemic stroke. In contrast to ischemia, intracranial bleeding induces intense vasospasm in neighboring vessels 4 to 12 days after the initial bleed, increasing the risk for significant cerebral ischemia. The mental status evaluation may be used to guide therapy, with an intact mental status implying adequate cerebral perfusion.

Markedly elevated pressures increase the risk of rebleeding. The goal is a 20% to 25% reduction in blood pressure over 6 to 12 hours, but not to less than 160 to 180/100 mm Hg.⁵⁶ Labetalol or nicardipine are the preferred agents, as they have no significant adverse effects on ICP or CPP.⁴ There are clinical data to show that treatment with oral nimodipine within 4 days of the acute event decreases vasospasm and cerebral ischemia.⁵¹ Nimodipine may also directly protect against ischemic damage to nerve cells by blocking calcium uptake into cells.

Intracerebral Hemorrhage

Intracerebral hemorrhage accounts for 10% to 20% of all strokes.⁵⁷ Hypertension is a major risk factor; 75% of affected individuals have preexisting hypertension.⁵⁸ Although patients with intracerebral hemorrhage may present with nausea, vomiting, change in mental status, hypertension, headache, and a focal neurologic examination, the definitive diagnosis must be made by neuroimaging. Unlike ischemic stroke, where blood pressure generally returns to normal within 24 to 48 hours, in intracerebral hemorrhage, the most rapid decline in blood pressure occurs in the first 24 hours, but it may remain elevated for 7 to 10 days.⁵² The hematoma compresses normal tissue, creating an area of ischemia, increasing ICP and further decreasing CPP. Autoregulation is altered, making cerebral perfusion critically dependent on systemic blood pressure.⁵⁹

There is no clear consensus on the appropriate treatment of hypertension in the setting of acute intracranial hemorrhage. The decision to treat or not treat blood pressure should be made based on individual considerations including baseline blood pressure, etiology of hemorrhage, age, and elevated ICP. The central issue is whether aggressive lowering of blood pressure reduces the risk of intracerebral bleeding without disrupting blood flow to collateral areas. Some argue that decreasing blood pressure lowers the risk of hemorrhage extension, edema, and associated systemic complications, particularly when systolic blood pressure exceeds 200 mm Hg, a level associated with hematoma growth in some studies.⁵⁷⁻⁵⁹ A retrospective analysis of 76 patients with intracerebral hemorrhage and hypertension showed that maximum systolic blood pressure was significantly associated with hematoma enlargement, particularly if the systolic blood pressure was ≥ 160 mm Hg.⁶⁰ Others argue that not treating hypertension allows continued perfusion of areas at risk from low blood flow.⁵⁹ It was previously believed that rebleeding was rare in the first 24 hours. More recent data suggest that it is more common than thought, occurring in up to a third of affected individuals.^{58,61} The greatest risk is in the first few hours after the initial insult.^{61,62} An increased risk of bleed is associated with an initial large irregular bleed,⁶³ coagulopathy, liver disease,⁶⁴ and a low platelet count.⁶⁴ There is consensus on the following issues. (1) Aggressive lowering of blood pressure using intravenous medication and blood pressure monitoring every 5 minutes should be considered when the systolic blood pressure is over 200 mm Hg or the MAP is over 150 mm Hg. (2) In the setting of suspected intracranial hypertension, ICP should be monitored and consideration given to aggressive lowering of the blood pressure with continuous or intermittent intravenous medication when the systolic blood pressure is over 180 mm Hg or the MAP is over 130 mm Hg, keeping the CPP above 60 to 80 mm Hg. The recent randomized controlled trial INTERACT2 supports the safety of this approach. In this study, half of 2839 patients received intensive treatment to lower their blood pressure to a target systolic level of <140 mm Hg within 1 hour. While there was no significant reduction in death, patients assigned to intensive treatment had improved functional outcomes at 3 months.³³ (3) If there is no suspected elevation of the ICP and the systolic blood pressure is >180 or MAP >130, consider lowering to a target blood pressure of 160/90 mm Hg or an MAP of 110 mm Hg.

There is no consensus on the agent of choice. Concern revolves around the impact of different antihypertensives on ICP. Common to all agents is a decrease in MAP and a decrease in CPP. Vasodilating agents may increase CBF and in the setting of decreased cranial compliance may potentially increase ICP, further decreasing CPP.^{37,59} The

combination of decreased cerebral compliance, decreased CBF, and altered autoregulation—as occurs in chronic hypertension—makes the administration of any antihypertensive agent potentially dangerous. No large randomized studies are available to guide therapy. Combination α - and β -blockers are recommended when antihypertensive treatment is indicated in intracerebral hemorrhage. Risks of this therapy include worsening of bradycardia associated with the Cushing response. However, in the setting of normal cranial compliance and an increased ICP, vasodilators are probably safe. Because of the very high levels of circulating catecholamines with an intracerebral bleed, β -blockade is added when vasodilator therapy alone is ineffective.

Head Trauma

Head trauma complications include skull fractures, epidural hematomas, subdural hematomas, intracerebral hematomas, and diffuse axonal damage. With trauma, there is often edema. Acute increases in ICP are initially prevented by flow of blood and CSF from the cranial vault. However, with increasing edema, ICP eventually increases. In most trauma centers, ICP monitoring has become the standard of care.⁶⁵ Anywhere from 31% to 61% of patients with a closed head injury may have defective autoregulation.⁶⁶ If autoregulation is intact, increasing the MAP will cause vasoconstriction and produce no change in ICP. With altered autoregulation, increasing the MAP may cause vasodilatation, increasing blood volume and leading to edema and increased ICP. The goal is to maintain a minimum CPP of 70 mm Hg and an MAP above 90 mm Hg. If an antihypertensive agent is needed, a major consideration is its impact on ICP. A combination α - and β -blockers or nicardipine may be preferred when there is decreased intracranial compliance and increased ICP.^{67,68} In the absence of intracranial hypertension, vasodilators may be preferred.

Aortic Dissection

Aortic dissection begins with a tear in the intima of the aorta that is propagated by the aortic pulse wave. Myocardial contractility, heart rate, and blood pressure contribute to the aortic pulse wave. There are two types of aortic dissections, type A and type B. Type A dissections are often associated with a tear in the intima of the proximal aorta next to a coronary artery and may extend to the aortic arch.⁶⁹ Type B dissections occur in the descending aortic arch and usually begin with an intimal tear next to the subclavian artery.⁷⁰ Risk factors for dissection include advanced atherosclerosis, Marfan syndrome, Ehlers-Danlos syndrome, and coarctation of the aorta.⁷¹ Symptoms occur as the expanding hematoma causes pressure on the vasculature. This may cause myocardial infarction, stroke, spinal cord or bowel infarction, and acute renal failure. Kidney ischemia may develop, leading to refractory hypertension.⁷² Dissection to the aortic root can precipitate acute aortic insufficiency, and rupture of the ascending aorta leads to hemopericardium and tamponade.⁷³

Both types of dissections may present with severe, often tearing pain in the chest, back, or abdomen, accompanied by diaphoresis, nausea, or vomiting. Dissection is often but not always associated with hypertension.⁷⁴ Discrepancies in peripheral pulses may be observed. Chest pain is reportedly present in only half of individuals with type B dissections.⁷⁵ The diagnosis may be confirmed with CT or MRI. Multiplane transesophageal echocardiography is also used. Type A dissections usually require surgery to prevent the catastrophic consequences of great-vessel occlusion, aortic insufficiency, or tamponade. Type B dissections may usually be treated medically^{76,77} unless there is rupture, in which case open or endovascular repair is indicated. A recent meta-analysis suggested that endovascular repair may be preferred.⁷⁶

Treatment for both type A and type B dissections is initiated based on clinical suspicion alone, given the high mortality associated with this entity. The first goal of treatment is to decrease myocardial contractility and heart rate with a β -blocking agent. Esmolol has advantages in the acute setting due to its short half-life and ability to titrate to effect. Next, the blood pressure is reduced to the lowest tolerable level

until pain is relieved. Relief of pain suggests arrest of ongoing aortic dissection. The most widely used agent is nitroprusside, titrated to a systolic pressure of 100 to 120 mm Hg or to as low as 70 to 80 mm Hg. Prior treatment with β -blockade prevents reflex cardiac stimulation and a potential increase in the aortic pulse wave seen with nitroprusside. Heart rate must be maintained between 60 and 80 beats per minutes. Even normotensive individuals should be treated with antihypertensive medications to keep the heart rate and shear forces low.

Pulmonary Edema

Many patients who present with pulmonary edema have long-standing antecedent hypertension with concentric left ventricular hypertrophy and well-preserved systolic contraction.^{78,79} They develop acute diastolic dysfunction in response to abrupt increases in cardiac afterload due to increased systemic blood pressure.⁸⁰ With poor diastolic relaxation, the left ventricle requires markedly elevated filling pressures, leading to pulmonary venous hypertension and edema. The therapeutic goal is to decrease afterload, improve diastolic relaxation, and decrease pulmonary pressure. Vasodilators are the agents of choice, as they improve diastolic relaxation and lower pulmonary venous pressure.⁸¹ A β -blocker may also be used. Nitroprusside is often used because it reduces preload and afterload, improving left ventricular function and reducing myocardial oxygen demand. Modest decreases in pressure improve symptoms markedly. In less emergent settings, ACE inhibitors or calcium channel antagonists have been shown to improve diastolic function and cause regression of concentric ventricular hypertrophy.⁸²

In patients with left ventricular failure secondary to poor systolic function, vasodilators are the agents of choice. Nitroglycerin is preferred with cardiac ischemia. Nitroprusside may be used in patients refractory to nitrites. Whereas nitroglycerin dilates intercoronary collateral vessels more than small resistance arterioles and improves perfusion of ischemic myocardium, nitroprusside dilates resistance arterioles predominantly, thereby resulting in a potential steal of blood flow away from ischemic areas. Diuretics are used to reduce left ventricular end-diastolic volume.

In the setting of acute myocardial infarction, acute catecholamine release and sympathetic outflow contribute to hypertension. The hypertension usually resolves in a few hours with sedation and pain control alone. Diastolic blood pressures over 100 mm Hg should be treated with nitroglycerin. The pressure is rapidly, but cautiously, reduced to near-normotensive levels; overshoot hypotension can worsen coronary perfusion. Therapy can usually be stopped within 24 hours. There is considerable evidence that the early use of β -blocking agents may reduce ultimate infarct size independent of blood pressure control.⁸³

Perioperative Hypertension

Perioperative hypertension is a major risk factor for the development of postoperative hypertension.⁸⁴ Whenever possible, it is preferred to postpone elective surgery until the blood pressure has been well controlled over days to weeks. However, when waiting is not an option, lowering the blood pressure to below 180/110 prior to noncardiac surgery is recommended.⁸⁴ In patients with chronic hypertension on adequate treatment, oral medications should be taken the morning of surgery. Adequate blood pressure control reduces the risk of bleeding from suture lines, premature graft closure, and ischemic damage to organs at risk.

Induction of anesthesia and surgical stimuli increase sympathetic activity, causing elevated blood pressure both intra- and postoperatively. This response may be exaggerated in uncontrolled hypertension, with decreased use of deep anesthesia and absence of prolonged sedation. As anesthesia continues, there is generally a fall in blood pressure. Rapid and wide fluctuations in blood pressure leading to intraoperative hypotension, stroke, myocardial ischemia, or acute renal failure are more common in individuals with a hypertensive history.

Patients taking hypertensive therapy prior to surgery should continue treatment after surgery, changing to an equivalent intravenous medication if they are unable to take oral medications. If patients have been on a β -blocker or clonidine, this medication should be continued postoperatively to prevent rebound hypertension. Effective pain control and avoidance of hypoxia may be sufficient to treat the hypertension. If intravenous medication is necessary, nitroglycerin is preferred for the post-coronary bypass patient. Fenoldopam, with its impact on increasing renal blood flow, is also recommended, especially in clinical settings where renal ischemia is a risk. Clevidipine has been gaining popularity in this setting because of its rapid onset and short duration of action with limited effect on cardiac preload and output. However, there is limited experience with this drug, and cost is an issue.⁸⁵

Catecholamine-Associated Hypertension

Hypertensive emergency related to excess catecholamine secretion can result from the ingestion of sympathomimetic agents such as cocaine, amphetamines, phencyclidine, phenylpropanolamine (diet pills), decongestants such as ephedrine and pseudoephedrine, and other agents including atropine, ergot alkaloids, and tricyclic antidepressants. It may also be caused by tyramine ingestion in conjunction with monoamine oxidase (MAO) inhibitor therapy, autonomic dysfunction, withdrawal from certain antihypertensive medications, and pheochromocytoma (Box 87-3). Critically elevated pressures can result and cause myocardial infarction, aortic dissection, and stroke.

Pheochromocytoma is a very rare cause of hypertension.⁸⁶ Excess catecholamine secretion by the tumor results in a sustained elevation of blood pressure in the majority of cases, while peripheral catecholamine uptake and storage lead to paroxysmal symptoms when the catecholamines are released in response to stimuli. Symptoms of pheochromocytoma include headache, palpitations, hypertension, anxiety, abdominal pain, and diaphoresis. Patients may present with orthostatic changes in blood pressure, a clue to the diagnosis.⁸⁷ For the patient with hypertensive emergency, the treatment of choice is the short-acting parenteral α -antagonist, phentolamine. Following blood pressure reduction, β -blockade is generally added to control tachycardia or arrhythmias. As in all catecholamine excess states, β -blockers should not be used as initial therapy. Loss of β -adrenergically mediated vasodilatation leaves α -adrenergically mediated vasoconstriction unopposed and results in increased pressure. An oral regimen of the nonselective α -antagonist, phenoxybenzamine, can be used in less critical situations. Labetalol has been effective in treating hypertension related to pheochromocytoma in selected patients. However, as its β -blockade exceeds its α -blocking effect, severe hypertension has been reported.⁸⁸

Gestational Hypertension/Preeclampsia/Eclampsia

Gestational hypertension is defined as a systolic blood pressure of at least 140 mm Hg and a diastolic blood pressure of at least 90 mm Hg on two separate blood pressure measurements done 6 hours apart. It occurs after 20 weeks of pregnancy in patients known to previously be normotensive.⁸⁹ Up to 50% of these women develop preeclampsia if gestational hypertension develops before 30 weeks of gestation. *Preeclampsia* is defined as gestational hypertension with 300 mg or more

of protein on a 24-hour urine (urine dipstick 1+). A 24-hour urine is necessary because dipstick urine protein correlates poorly with 24-hour urine protein in gestational hypertension.⁹⁰ Preeclampsia should also be suspected in patients with hypertension developing after 20 weeks' gestation and associated with nausea, vomiting, cerebral symptoms, abnormal liver function tests, and thrombocytopenia, even in the absence of proteinuria. Preeclampsia develops in 5% of all pregnancies and occurs twice as often in primigravida versus multigravida women.⁹¹ Preeclampsia also appears in women with a history of multiple pregnancies but with a new partner.⁹¹ In the setting of molar pregnancy, it is seen in up to 70% of individuals.⁹² During normal pregnancy, blood pressure is initially decreased and then slowly rises toward the normal range during the third trimester. In preeclampsia, intravascular volume is low despite peripheral edema, and the renin-angiotensin system is activated. Progression to seizures defines eclampsia and may occur with diastolic pressures of as low as 100 mm Hg. Clinical treatment includes bed rest and parenteral magnesium.

With regard to hypertensive treatment in pregnancy, the optimal blood pressure has not been defined. The goal is to prolong the pregnancy until the fetus can be delivered. In the case of mild preeclampsia, there are no large studies to guide therapy.⁹¹ With more severe preeclampsia, treatment is given to prevent cerebral hemorrhage. The recommendation is to initiate antihypertensive therapy when the systolic blood pressure is above 160 mm Hg or the diastolic blood pressure is above 110 mm Hg. Intravenous labetalol and hydralazine have long been considered first-line medications to keep the systolic blood pressure 140 to 155 mm Hg and the diastolic blood pressure 90 to 105 mm Hg.⁹¹ However, hydralazine use can be associated with severe hypotension and maternal and fetal complications.⁹³ A recent meta-analysis reported good blood pressure control with the use of oral nifedipine. Fewer doses were required and less time needed to achieve control, and the adverse effect profile was similar to intravenous labetalol.⁹⁴ In an updated opinion, the American College of Obstetricians and Gynecologists Committee adds oral nifedipine as a first-line therapy.⁹⁵ Concern for neuromuscular blockade and severe hypotension with the contemporaneous use of nifedipine and magnesium sulfate were not substantiated in a large retrospective review.⁹⁶ However, because both drugs are calcium antagonists, careful monitoring is advisable. Nitroprusside should be avoided because of the risk of cyanide toxicity in the fetus. ACE inhibitors should also be avoided because of their potential impact on the fetal kidney.

Other Hypertensive Situations

The renal crisis of scleroderma is an aggressive form of malignant hypertension in which proliferative endarteritis precedes hypertension. Ischemic-induced activation of the renin-angiotensin system causes the hypertension. The incidence of this condition among patients with scleroderma ranges from 8% to 13%, and it is more common among blacks.⁹⁷ Progression to ESRD occurs in 1 to 2 months without treatment. Aggressive pressure control with ACE inhibitors leads to a long-term survival of about 50% to 70%.⁹⁸

Hypertension is a feature of both primary and secondary antiphospholipid antibody syndromes, occurring in up to 93% of patients.⁹⁹ Malignant hypertension occurs in this syndrome secondary to both microvasculopathy and emboli to the renal artery. Antihypertensive treatment is similar to that for malignant hypertension. Successful treatment outcomes have been reported with anticoagulation.⁹⁹

One-fourth of patients with extensive second- or third-degree burns develop severe hypertension in the first few days, likely due to high levels of circulating catecholamines and renin. Nitroprusside or phentolamine (in countries where it is still available) are other treatments.

Patients with transverse spinal cord lesions at the T6 level or higher, including patients with Guillain-Barré syndrome, have dysreflexia in which noxious stimuli in dermatomes below the level of lesion trigger a massive sympathetic discharge. This leads to severe hypertension, bradycardia, diaphoresis, and headache. In 90% of patients, distention

of the bladder or bowel causes the dysreflexia, and prompt decompression leads to resolution of hypertension.¹⁰⁰ Drugs that have been used successfully in treating this condition include nitroprusside, phentolamine, and labetalol.

HYPERTENSIVE URGENCY

Hypertensive urgency refers to patients in whom blood pressure is severely elevated, but based on detailed history, physical examination, and laboratory evaluation, there is no evidence of acute end-organ damage related to the current episode of hypertension, although there may be evidence of previous hypertension-induced end-organ damage. Although long-term control of blood pressure in this setting can prevent complications due to stroke, myocardial infarction, or congestive heart failure, there is no evidence that acute reduction of blood pressure results in any improvement in short- or long-term prognosis. Unfortunately, the term *urgency* is a misnomer and has led to overly aggressive management of many patients. Aggressive treatment with intravenous drugs or even oral agents, such as clonidine or nifedipine, to rapidly lower blood pressure can lead to cumulative effects causing hypotension, sometimes following discharge from the emergency room. A more appropriate clinical term to describe this condition is severe uncomplicated hypertension, because there is no need for urgent reduction of blood pressure as would be required in patients with true hypertensive emergencies (Box 87-4).

BOX 87-4 Severe Uncomplicated Hypertension

SEVERE HYPERTENSION (DIASTOLIC >115 mm Hg) IN ASSOCIATION WITH ONE OR MORE OF THE FOLLOWING

Chronic renal failure
Chronic congestive heart failure
Stable angina
Previous myocardial infarction
Transient ischemic attacks
Previous cerebrovascular accident

The treatment of choice is gradual pressure reduction over a few days in the outpatient setting. The choice of antihypertensive agent is based on ease of administration and side-effect profile rather than on rapid blood pressure reductions. Frequently, restarting a previously effective regimen is all that is necessary. It is critically important to follow these patients over the next 24 to 48 hours to ensure the blood pressure is appropriately reduced. While medicolegal issues may pressure physicians into loading these patients with medication to observe on-the-spot control of their blood pressure, this practice has been questioned as having no clear rational scientific basis.

■ PATHOPHYSIOLOGY OF SHOCK

Circulatory shock represents a final common pathway of cardiovascular failure. Septic shock is the most common cause of shock followed by cardiogenic and hypovolemic shock.¹ Mortality remains high, particularly for patients with septic and cardiogenic shock, where it ranges from 40% to 60%, respectively.^{2,3} From a physiologic perspective, circulatory shock is defined as a syndrome in which blood flow is inadequate to meet cellular metabolic requirements.⁴ Clinically, shock is manifested by organ hypoperfusion, which is most evident in the skin and peripheries, kidneys, and brain. The principal signs of circulatory shock are as follows: cool, clammy, and cyanotic extremities; decreased pulses; oliguria with a urine output <0.5 mL/kg per hour; and confusion, disorientation, and obtundation.

Mechanisms Underlying Impaired Cardiovascular Performance

The development of shock is related to alterations in the components of the circulatory system that regulate cardiovascular performance. The first component is intravascular volume, which regulates mean circulatory pressures and venous return to the heart. Decreases in intravascular volume limit venous return to the heart and cardiac output. The heart is the second component. Cardiac output is determined by heart rate, contractility, and loading conditions. Abnormalities in rhythm and heart rate may limit cardiac output. Impaired cardiac contractility decreases effective ventricular ejection and compromises stroke volume. Abnormalities in valvular function may also limit cardiac output. The third component is the resistance circuit; it consists of the arteriolar bed, where the major decreases in vascular resistance occur. Arteriolar tone plays an important role in ventricular loading conditions, arterial pressure, and distribution of systemic blood flow. Excessive decreases in arteriolar tone lead to hypotension and limit effective organ perfusion, whereas excessive increases in arteriolar tone impede cardiac ejection by increasing ventricular afterload. Differences in arteriolar tone between organs can result in maldistribution of blood flow and mismatching of blood supply with tissue metabolic demands. The capillaries are the fourth component. They are the site of nutrient exchange and fluid flux between the intravascular and extravascular spaces. Increases in capillary permeability result in tissue edema and loss of intravascular volume. Decreases in capillary cross-sectional area, secondary to either obstruction or impairment in endothelial cell function, compromise nutrient blood flow. The opening of arteriovenous connections, which bypass the capillary network, may play a role in tissue hypoperfusion. The venules are the fifth component. They are the site of the lowest shear stress in the circulatory system and are thus the site most prone to occlusion from alterations in cell rheology. Venular resistance contributes 10% to 15% of total vascular resistance. Increases in venular tone increase capillary hydrostatic pressures, thereby promoting the extravascular movement of fluid. The sixth component is the venous capacitance circuit. More than 80% of the total blood volume resides in large capacitance vessels. Increases in venous tone decrease venous capacitance, redistributing blood volume centrally and thereby increasing venous return to the heart. Decreases in venous tone increase venous capacitance and decrease effective arterial blood volume and venous return. The seventh component is mainstream patency. Obstruction of the systemic or pulmonary circuit

impedes ventricular ejection, while venous obstruction limits venous return to the ventricles.

Hemodynamic Assessment

Circulatory performance can be assessed from hemodynamic parameters. A low heart rate may limit cardiac output, whereas an increased heart rate can compromise stroke volumes by limiting ventricular filling times. Bradyarrhythmias indicate structural abnormalities, effects of drugs, hypoxia, or other metabolic stimuli. Severe bradyarrhythmias can also represent reflex-mediated responses, as occurs in cases of severe hemorrhagic shock and acute inferior wall myocardial infarction. Tachyarrhythmias may be due to underlying cardiac disease or pharmacologic or environmental stimuli. Alternatively, increases in the heart rate may reflect compensatory responses to maintain cardiac output.

In patients with circulatory shock, blood pressure should be monitored using intravascular measurements.⁴ Vasoconstriction related to compensatory mechanisms to maintain arterial pressure and the use of pharmacologic agents limits the accuracy of noninvasive measurements. This is particularly true in hypodynamic forms of circulatory failure.

For most vital organs, autoregulatory and neuronal mechanisms maintain blood flow independent of blood pressure at a mean arterial pressure of 60 to 130 mm Hg. At either higher or lower levels of pressure, blood flow becomes linearly dependent on blood pressure. Diseases such as hypertension can shift this relationship and increase the critical level of arterial pressure required for organ perfusion. Similarly, impaired autoregulatory mechanisms present in a variety of pathologic states expand the range of pressure-dependent blood flow.

The level of arterial pressure is not a reliable indicator of circulatory performance and tissue perfusion.^{5,6} In states of hypodynamic circulatory shock such as traumatic injury and cardiac failure, hypotension is a late marker of critical hypoperfusion. As cardiac output falls, blood pressure is initially maintained by increases in peripheral vascular resistance largely mediated by the sympathoadrenal system. It is only after these mechanisms have been exhausted that hypotension develops. Accordingly, tissue hypoperfusion may be present despite normal levels of blood pressure as blood flow is redirected toward more vital organs. Conversely, hypotension may exist without evidence of organ hypoperfusion. In some vasodilated states, increases in cardiac output maintain vital organ blood flow despite decreased levels of arterial pressure.

Pulmonary artery wedge pressure and central venous pressure are indirect measures of ventricular preload. These measurements correlate poorly with blood volume, end-diastolic volumes, and fluid responsiveness.⁷ Filling pressures are determined by ventricular compliance, venous return, and systolic function. Factors such as ventricular interactions, positive airway pressure, and intrinsic cardiac disease may decrease ventricular compliance and lead to an overestimation of ventricular preload. Echocardiographic techniques can provide a more accurate assessment of ventricular loading conditions, while dynamic indicators such as pulse pressure variation, stroke volume variation, changes in caval diameter, and passive leg raising may provide greater insight into fluid responsiveness.^{8,9}

Cardiac output can be measured by multiple techniques.⁴ Pulmonary artery thermodilution has been augmented by less invasive techniques including transpulmonary thermodilution and lithium

dilution, echocardiography, esophageal Doppler, and arterial pulse contour analysis. Echocardiographic measurements and esophageal Doppler can be used to assess ventricular ejection and also provide diagnostic information regarding the presence of pericardial tamponade and valvular function. The response of stroke volume to changes in ventricular loading during fluid infusion is also useful to assess cardiac contractility. A good response indicates preserved cardiac function, while lack of response may be related to either cardiac dysfunction or inadequate fluid volumes. However, the adequacy of cardiac output in meeting tissue metabolic demands must be assessed independently by monitoring indices of tissue perfusion and oxygen metabolism. A low cardiac output may be adequate when metabolic requirements are decreased—for example, in deep sedation or hypothermia. In contrast, an increased cardiac output may not be adequate when metabolic requirements are increased or maldistribution of blood flow exists, such as in septic shock.

Systemic vascular resistance is an indicator of arterial tone; it is calculated from cardiac output and arterial pressure. Increases in systemic vascular resistance are due to vasoconstriction and represent compensatory mechanisms directed at maintaining blood pressure in the setting of a decreased cardiac output. Excessive increases in vascular resistance increase ventricular afterload and the impedance to ejection. Decreases in vascular resistance are due to vasodilation, decreases in blood viscosity, or presence of arteriovenous connections. Vasodilation may be pathologic, as occurs in septic shock and liver disease, or it may be adaptive, as occurs in hyperdynamic stress following major surgery and traumatic injury. Venous tone is much harder to assess clinically. In most cases, changes in venous tone parallel changes in arterial tone. Modest increases in central venous pressures in the setting of large-volume infusion and the absence of intravascular volume loss suggest decreased venous tone.

■ CLASSIFICATION OF SHOCK

Hinshaw and Cox proposed a classification of circulatory shock involving four subsets: hypovolemic, cardiogenic, distributive, and obstructive.¹⁰ This classification can be simplified into two categories with typical hemodynamic profiles (Table 88-1). The first category, hypodynamic shock, includes the hypovolemic, cardiogenic, and obstructive shock subsets. The second category, hyperdynamic shock, includes the distributive shock subset.

The central features of hypodynamic shock are a low cardiac index and a high-resistance vasoconstricted state. Increased oxygen extraction and lactic acidosis usually parallel the decrease in cardiac output. In cases of hypodynamic shock, the development of organ dysfunction is directly related to inadequate global blood flow. Common causes of hypovolemic shock are hemorrhage, dehydration, and massive capillary leak. Acute decreases in blood volume of 25% result in tachycardia and orthostatic hypotension. The loss of 40% of blood volume is associated with a severe hypotension and clinical shock. Decreased filling pressures are the hallmark of hypovolemic shock, in contrast to cardiogenic shock in which filling pressures are elevated. Acute myocardial infarction involving 40% or more of ventricular mass is the most common cause of cardiogenic shock. Cardiomyopathies and severe valvular lesions are other important causes of cardiogenic shock.

Severe stress may also induce severe reversible cardiac dysfunction. Finally, obstructive shock is most commonly due to pericardial tamponade, acute pulmonary embolism, and tension pneumothorax. Dynamic obstruction to left ventricular output may also lead to circulatory shock. Since filling pressures are usually increased in these settings (owing to outflow obstruction, impaired ventricular filling, and decreased ventricular compliance), distinguishing between obstructive shock and cardiogenic shock can be difficult.

Hyperdynamic circulatory shock is characterized by a high cardiac index and a low-resistance vasodilated state. Filling pressures may be increased or normal, depending on volume status and myocardial competence. Common causes of hyperdynamic shock include sepsis, anaphylaxis, drug intoxications, spinal shock, and adrenal insufficiency. The underlying hemodynamic defect is maldistribution of blood flow and/or blood volume such that effective nutrient blood flow is compromised. In contrast to hypodynamic shock, oxygen extraction may be normal or decreased despite evidence of hypoperfusion.¹¹ Direct mediator-related effects coupled with tissue hypoperfusion lead to cellular injury and organ dysfunction in patients with septic shock.

A considerable overlap may exist between these different syndromes. Early in septic and anaphylactic shock, prior to fluid infusion, a significant hypovolemic component usually exists. Hypovolemia may also be present in a small group of patients presenting with shock secondary to acute myocardial infarction. In the presence of severe sepsis-related myocardial depression, patients with septic shock can develop a hypodynamic profile. Similarly, patients in cardiogenic shock after myocardial infarction and cardiac surgery may demonstrate significant vasodilation due to the activation of mediator cascades while on cardiopulmonary bypass.¹² Alternatively, dynamic left ventricular outflow obstruction related to systolic anterior movement of the mitral valve may complicate ischemic and stress-related cardiogenic shock.¹³

Progression of Shock

Critical reductions in tissue perfusion elicit a complex set of reflexes that are directed at maintaining cardiac output and arterial pressure.¹⁴ Activation of the sympathetic nervous system increases heart rate and contractility. The release of catecholamines, angiotensin, vasopressin, and endothelins increases arteriolar and venous tone, thereby increasing arterial blood pressure and shifting blood volume from the capacitance vessels to the central circulation. In addition, blood flow is redirected from skeletal muscle, subcutaneous tissue, and splanchnic circulation to the heart and brain. Vasopressin and activation of the renin-angiotensin system serve to enhance water and sodium retention, thereby protecting intravascular blood volume.

Progression of the shock state is marked by further declines in blood pressure that compromise coronary perfusion and cardiac performance. Increases in peripheral vascular resistance increase afterload and impede left ventricular ejection. Terminal phases of shock are marked by vasomotor dysfunction and loss of arteriolar tone with paradoxically increased venular resistance. The resulting increase in capillary hydrostatic pressure coupled and associated with increased microvascular permeability leads to a loss of intravascular volume with worsening of the shock state. Leukostasis and changes in erythrocyte rheology further impair microvascular blood flow.

TABLE 88-1 Circulatory Shock Hemodynamic Profiles

| | MAP | PAWP | CO | SVR | Svo ₂ | LACTATE |
|---|-----|------|----|-----|------------------|---------|
| HYPODYNAMIC | | | | | | |
| Hypovolemic hemorrhage, dehydration | ↓ | ↓ | ↓ | ↑ | ↓ | ↑ |
| Cardiogenic myocardial infarction | ↓ | ↑ | ↓ | ↑ | ↓ | ↑ |
| Obstructive pulmonary embolism, pericardial tamponade, tension pneumothorax | ↓ | ↔↑ | ↓ | ↑ | ↓ | ↑ |
| HYPERDYNAMIC | | | | | | |
| Distributive sepsis, adrenal insufficiency, anaphylaxis | ↓ | ↔↓ | ↔↑ | ↓ | ↔↑ | ↑ |

CO, cardiac output; MAP, mean arterial pressure; PAWP, pulmonary arterial wedge pressure; Svo₂, venous oxygen saturation; SVR, systemic vascular resistance.

This pathophysiology is altered in hyperdynamic forms of circulatory failure such as septic shock, in which inflammatory mediators play a prominent role.¹⁵ These patients are characterized by arterial and venous vasodilation coupled with an increased cardiac output. The influence of vasodilatory substances, such as nitric oxide, predominates over the effects of endogenous and exogenous vasopressor substances. In some forms of vasodilatory shock, inappropriately low levels of vasopressin and cortisol may contribute to refractoriness to catecholamines.¹² Decreases in capillary cross-sectional area, secondary to the interactions of activated leukocytes, platelets, endothelial cells, and the clotting cascade, limit effective nutrient blood flow despite the increase in cardiac output.¹⁶ Progressive hypotension, which is refractory to fluid infusion and vasopressors, results in worsening tissue hypoperfusion, acidosis, and organ failure. A hypodynamic circulation develops as a terminal event.

Oxidative Metabolism in Shock

The primary metabolic defect in circulatory shock is impaired oxidative metabolism with resulting cellular and organ failure. This impairment is most commonly due to decreases in tissue oxygen supply caused by either global decreases in blood flow or maldistribution of blood flow at a regional or microcirculatory level. Systemic oxygen consumption may initially be increased yet inadequate to meet tissue metabolic requirements; however, the terminal phases of all forms of shock are characterized by decreases in oxygen consumption. In experimental studies, mortality is directly related to the cumulated deficit in oxygen metabolism.¹⁷

Oxygen delivery is determined by cardiac output, hemoglobin concentration, and arterial oxygen saturation. Under normal circumstances, oxygen consumption is independent of oxygen delivery and cardiac output (Fig. 88-1). Increases in cellular oxygen extraction, from a normal level of 25% to a maximum of level of 80%, maintain oxygen consumption because blood flow is reduced. When oxygen

extraction is maximized, a critical level of oxygen delivery (DO_{2crit}) is reached below which oxygen consumption decreases and anaerobic metabolism ensues. Alterations in vasomotor reflexes caused by sepsis or drugs limit maximal oxygen extraction, resulting in critical tissue hypoxia and anaerobic metabolism at higher levels of oxygen delivery.¹⁸

Aerobic adenosine triphosphate (ATP) generation is dependent on glycolysis occurring in the cytoplasm and oxidative phosphorylation occurring in the mitochondria (Fig. 88-2). Under anaerobic conditions, ATP generation is limited to the two moles of ATP generated in the cytoplasm, compared with the 38 moles of ATP generated aerobically. The decreased entry of pyruvate into the citric acid cycle results in the accumulation of lactic acid and the generation of additional hydrogen ions from the hydrolysis of ATP. Accordingly, the presence of lactic acidosis serves as an indicator of critical cellular deficits in high-energy phosphate metabolism. The normal level of lactate is 0.4 to 1.2 mEq/L. Levels greater than 1.5 mEq/L are associated with an increased mortality rate in septic shock.¹⁹

Oxidative metabolism may also be impaired by mechanisms independent of tissue hypoperfusion. Inflammatory mediators, including nitric oxide, oxygen radicals, calcium, and tumor necrosis factor, impair mitochondrial function. Down-regulation of genes transcribing proteins important in mitochondrial biogenesis, mitochondrial swelling, and decreased mitochondrial complex activity has been observed in patients with septic shock.^{20,21} Serum from patients with septic shock has also been demonstrated to inhibit mitochondrial respiration and decrease cellular ATP concentration *in vitro*.²² Similarly, impaired mitochondrial function has been described in animal models of traumatic and hemorrhagic shock. The specific role of these mitochondrial abnormalities in organ dysfunction in shock remains to be determined.

The accumulation of tissue carbon dioxide (CO_2) parallels the decrease in oxygen metabolism in circulatory shock.²³ Increases in tissue CO_2 levels are manifested by venous hypercapnia and decreases in venous pH. The resulting widening of the arterial-venous CO_2 gradient is proportional to the degree of circulatory failure.²⁴ The normal

FIGURE 88-1 ■ Oxygen consumption–oxygen delivery relationships. Oxygen consumption (VO_2) is independent of oxygen delivery (DO_2) until a critical level of DO_2 is reached at which oxygen extraction is maximized. At that level of oxygen delivery (DO_{2crit}), VO_2 becomes linearly dependent on DO_2 , and anaerobic metabolism manifested by lactic acidosis ensues. This relationship shifts upward and to the right when the ability of the tissues to extract oxygen is impaired due to alterations in the distribution of blood flow.

FIGURE 88-2 ■ Cellular oxidative metabolism. Glucose is metabolized anaerobically in the cytoplasm and aerobically in the mitochondria under conditions of normal tissue perfusion. Under conditions of shock, high-energy phosphate generation (ATP) is limited to anaerobic pathways. Nitric oxide (NO), peroxynitrite ($ONOO^-$), and superoxide (O_2^-) are potential inhibitors of the electron transfer chain.

gradient is less than 5 mm Hg, and it increases to 40 mm Hg during cardiac arrest. Decreased clearance of CO₂ generated by oxidative processes is responsible for the initial increase in tissue CO₂ levels. With the onset of anaerobic metabolism, a tissue CO₂ excess is generated from the titration of anaerobically derived acids by bicarbonate. The increase in tissue CO₂ levels has been associated with impaired myocardial performance *in vitro*.

Monitoring Perfusion Failure

Controversy exists over the optimal manner in which to monitor tissue perfusion in patients with circulatory shock. Commonly used parameters, such as heart rate, arterial pressure, and cardiac output, correlate poorly with survival in critically ill patients.^{5,6} This is particularly true in patients with septic shock and traumatic injury, in whom underlying deficits in tissue perfusion may exist despite initial resuscitative efforts.²⁵ These observations have led to the use of indices of tissue oxygen metabolism as markers of tissue perfusion and the adequacy of resuscitative efforts.

Mixed venous oxygen saturation (SvO₂), measured on blood taken from the pulmonary artery, is used as an index of tissue oxygenation. Venous blood is in equilibrium with the tissues. Mixed venous blood, representing a weighted mean of all the venous effluents, reflects overall tissue oxygenation. Since increased oxygen extraction is the primary compensatory mechanism to maintain oxygen consumption, decreases in SvO₂ are an early marker of compromised tissue perfusion. In cardiogenic shock, SvO₂ tracks cardiac function and systemic perfusion.²⁶ The same is not true in septic shock and other settings where the relationship between venous blood and tissue oxygenation is altered by maldistribution of blood flow.¹¹ In these circumstances, the ability of the tissues to extract oxygen is limited by decreases in effective nutrient flow such that SvO₂ may be normal or increased despite the presence of tissue hypoxia and anaerobic metabolism. Accordingly, while mixed venous desaturation is indicative of tissue hypoxia, normal levels do not preclude tissue hypoperfusion.

Central venous oxygen saturation (ScvO₂), measured in samples taken from the superior vena cava and right atrium, serves as an alternative to SvO₂. In critically ill patients, ScvO₂ is generally 5% higher than SvO₂; however, the correlation is inconsistent depending, in part, on the location of the tip of the central venous catheter. In patients with septic shock and baseline ScvO₂ of 48%, improved survival was demonstrated when therapy was titrated to ScvO₂ ≥70%.²⁷ Subsequent reports in patients who were better resuscitated with baseline ScvO₂ ≥70% failed to demonstrate the same benefit of ScvO₂ monitoring.^{28,29}

Lactate concentration is a useful marker of critical hypoperfusion. Increases in lactate levels indicate the presence of anaerobic metabolism and tissue energy deficits. Although the initial blood level of lactate has prognostic significance, the inability to clear lactate over time is more discriminating.^{30,31} In patients with septic shock, factors other than hypoperfusion may contribute to lactate accumulation. These factors include increased muscle ATPase activity, increased hepatic flux of alanine from skeletal muscle, decreased pyruvate dehydrogenase activity, decreased hepatic clearance of lactate, and dysfunctional mitochondrial respiration. Despite these concerns, increases in lactate concentration are associated with decreases in the intracellular redox potential in patients with septic shock, suggesting that it is a useful marker of cellular energy metabolism.³² When titration of therapy to ScvO₂ >70% was compared with achieving a lactate clearance of 10% over 6 hours in patients with septic shock, the outcome was similar.³³

Oxygen consumption and oxygen delivery are global markers of systemic oxygen metabolism. Oxygen consumption, a measure of overall metabolic requirements, is calculated from cardiac index, hemoglobin, and arterial and venous oxygen saturation. It can also be measured directly from expired gases. Oxygen delivery is calculated from cardiac output, hemoglobin, and arterial saturation; it is a measure of the total amount of oxygen being delivered to the tissues.

Although increased values of oxygen consumption and oxygen delivery have been observed in survivors compared with nonsurvivors, considerable overlap exists between the two groups. Efforts to titrate therapy to values associated with survival, “optimal goals,” have produced mixed results.³⁴ These differences, in part, reflect the varying metabolic requirements of individual patients.

The decrease in CO₂ clearance in circulatory shock can be used to monitor ongoing perfusion failure. Widening of the gap between central venous and arterial pCO₂ to >6 mm Hg can be used to identify patients who may not be adequately resuscitated despite ScvO₂ >70%.³⁵ End-tidal CO₂ measurements are useful in monitoring perfusion during cardiopulmonary resuscitation. Cardiac arrest results in marked decreases in pulmonary blood flow and accompanying decreases in CO₂ excretion. End-tidal CO₂ values move toward zero during arrest and increase with successful resuscitation.³⁶

There have been multiple attempts to use measures of local or regional perfusion as indices of overall systemic perfusion. Toe temperature, subcutaneous oxygen tensions, transcutaneous oxygen tension, and laser Doppler are some examples of regional measures previously studied. Gastric tonometry and, more recently, sublingual tonometry have been used to assess vascular beds for CO₂ excess as a marker of systemic hypoperfusion. Currently, attention has been focused on two measures of microvascular blood flow.³⁷ One approach is the use of near-infrared spectroscopy to assess the level of oxygenated hemoglobin in the thenar skeletal muscle. Both the actual value and the response of tissue hemoglobin saturation to reactive hyperemia have been reported to predict survival. Other techniques, such as orthogonal polarization spectral imaging and sidestream dark-field imaging, have been used to directly visualize microcirculatory flow. Decreases in capillary blood flow have been observed in patients with septic shock and cardiogenic shock, which are correlated with survival. Evidence of persistent hypoperfusion using these measurements has been reported in patients with septic shock despite improvement in systemic indices of perfusion. Whether titration of therapy to these measures of local perfusion will impact the outcome remains to be determined.

Organ Failure

The primary causes of organ dysfunction in circulatory shock are ischemic injury, mediator-related organ dysfunction, and reperfusion injury. Ischemic injury occurs when anaerobic metabolism ensues and high-energy phosphate production falls below the level required to maintain cellular pumps and membrane integrity. It is the major factor contributing to organ failure in patients with cardiogenic and hypovolemic shock. The direct effect of inflammatory mediators, coupled with an ischemic injury, plays a major role in organ dysfunction in septic shock. Tumor necrosis factor, nitric oxide, and superoxide radicals are examples of mediators directly affecting cellular and organ function. Reperfusion injury occurs upon restoration of tissue perfusion following an absence of blood flow (Fig. 88-3). The initial injury is related to the release of oxygen radicals, increased membrane permeability, and intracellular calcium accumulation. The later phase involves cytokines, activated neutrophils, endothelial cell dysfunction, and microvascular occlusion.³⁸ Reperfusion injury may be important in hemorrhagic and traumatic shock; its role in cardiogenic shock and septic shock is less clear.

Cardiac dysfunction is related to ischemia and myocardial necrosis in shock secondary to myocardial infarction. Reperfusion injury may play a role in patients following acute coronary revascularization. Myocardial depressant substances such as nitric oxide and cytokines cause myocardial depression in patients in septic shock and possibly in hemorrhagic shock.³⁹ Impaired responsiveness to catecholamines and adrenergic receptor down-regulation occur in septic and cardiogenic shock. Increases in pulmonary vascular resistance cause right ventricular failure in patients with pulmonary embolism and may be important in septic shock, particularly when acute respiratory distress syndrome is present.

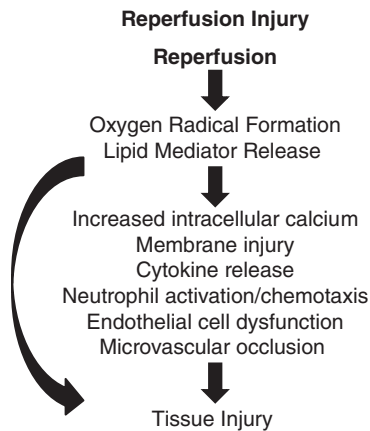

FIGURE 88-3 ■ Reperfusion injury. Under ischemic conditions, ATP is metabolized to hypoxanthine, and xanthine dehydrogenase is converted into xanthine oxidase. During reperfusion, superoxide is produced from hypoxanthine and oxygen by xanthine oxidase. Superoxide and its metabolites produce cellular injury and membrane disruption, resulting in the release of prostanoids and leukotrienes. The lipid mediators and oxygen radicals act as chemoattractants for neutrophils, which injure tissues through the release of elastases, proteases, and additional oxygen radicals.

Respiratory failure frequently complicates circulatory shock. Cardiac failure, fluid overload, and acute lung injury related to the release of inflammatory mediators and activation of neutrophils result in increased lung water and intrapulmonary shunt. Dead space may be increased due to either underlying disease and/or pulmonary vascular endothelial damage in acute lung injury syndromes. Decreased respiratory muscle perfusion, coupled with hypoxia and increased work of breathing, contributes to respiratory muscle failure. In patients with septic shock, inflammatory mediators may also directly impair respiratory muscle activity.⁴⁰

Renal dysfunction in shock is related to multiple mechanisms. Initially, as cardiac output decreases, glomerular filtration is maintained by increases in efferent arteriolar tone. Release of atrial natriuretic peptide because of increased atrial pressures may help protect renal blood flow in patients with cardiogenic shock. As shock progresses, the increases in afferent arteriolar tone result in renal ischemia and acute tubular necrosis. The activation of neutrophils, dendritic cells, and lymphocytes during sepsis/reperfusion also plays important roles in renal injury associated with shock.⁴¹

A characteristic pattern that involves centrilobar necrosis and marked transaminase elevation is observed in patients with ischemic hepatic injury associated with hypodynamic circulatory states.⁴² Activation of Kupffer cells and release of inflammatory mediators exacerbate ischemic injury in patients in septic and traumatic shock. In septic shock, canalicular cell function is impaired, resulting in intrahepatic cholestasis. Hepatic metabolic failure and impaired amino acid clearance are also features of septic shock.

Splanchnic mucosal blood flow is compromised early in shock, as blood flow gets redirected to more vital organs.⁴³ Splanchnic hypoperfusion related to shock and the use of vasopressors contribute to the development of stress ulceration, acalculous cholecystitis, intestinal necrosis, and pancreatitis. Loss of the integrity of the intestinal barrier leads to the release of inflammatory mediators into the mesenteric lymphatics and, less frequently, the translocation of bacteria, which in turn contribute to organ failure.

Thrombocytopenia is observed in a majority of patients with septic shock. The coagulation cascade is activated in septic and traumatic shock by the cytokines, tissue factors, and bacterial toxins. Disseminated intravascular coagulation is marked by impaired fibrinolysis and increased consumption of clotting factors. Clinical manifestations are

APPROACH TO CIRCULATORY SHOCK

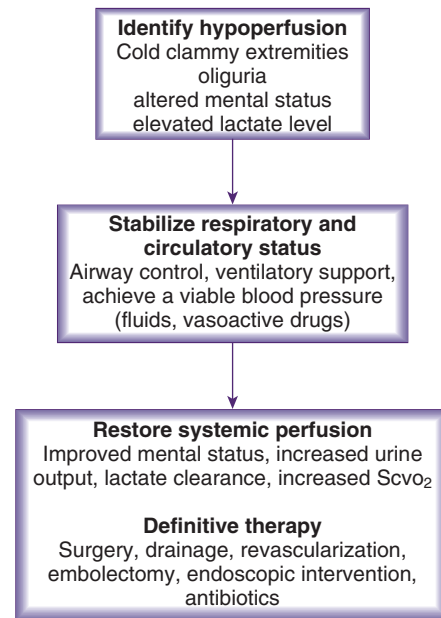

FIGURE 88-4 ■ Initial approach to patients with circulatory shock.

bleeding and microvascular thrombosis. Large-volume asanguineous fluid resuscitation may unmask these tendencies by restoring blood volume and additional hemodilution of clotting factors and platelets. The development of hypothermia exacerbates coagulopathies in patients with circulatory shock.

Disorientation and delirium are common in patients in shock. Hypotension, metabolic abnormalities, and hypoxia all contribute to neurologic dysfunction. Alterations in cerebral vascular reactivity and direct toxic effects of inflammatory mediators may also play a role in cerebral injury.⁴⁴ Severe hypotension, mean arterial pressure well below 60 mm Hg, can result in ischemic injury of the arterial border zones in the cortex and spinal cord.

Microvascular blood flow is impaired in all forms of circulatory failure.^{16,37,41} The microcirculation is characterized by heterogeneous blood flow and decreased capillary perfusion. Rheologic abnormalities of neutrophils and erythrocytes impede microvascular blood flow. Increased expression of neutrophil integrins, platelet P-selectin, and endothelial cell adhesion molecules results in cellular aggregation and microvascular obstruction. Decreased endothelial cell nitric oxide synthetase activity impairs normal vasodilatory reflexes and decreases the microvascular response to hypoxia.

Shock is associated with impairment of immunologic regulation of immunologic function. Immunosuppressive substances, including interleukin-10, prostaglandin E₂, and adenosine, are released that decrease cellular and humoral immunity. Altered signaling in afferent and efferent neural pathways contributes to impaired immune homeostasis.⁴⁵ Dendritic cell- and monocyte-mediated antigen processing is impaired, as is neutrophil function. Apoptosis of lymphocytes, dendritic cells, and monocytes is increased. A profile of decreased monocyte HLA-DR expression and impaired monocyte responsiveness to inflammatory stimuli has been associated with an increased risk of secondary infection and mortality.⁴⁶

CLINICAL ASPECTS OF SHOCK

Approach to Circulatory Shock

The approach to patients with circulatory shock involves restoration of cardiopulmonary stability and rapid assessment of the underlying disease process (Fig. 88-4). Patients should be assessed for clinical

evidence of organ hypoperfusion. Initial efforts should be directed at achieving a minimal level of blood pressure and ventilation associated with survival. The VIP approach prioritizes these efforts by focusing on ventilation, infusion, and pump activity.⁴⁷ Subsequent interventions should be focused on restoration of perfusion and organ function. A systematic approach, which incorporates physiologic endpoints, indices of systemic perfusion, and an algorithm for therapeutic interventions based on the pathophysiology of the underlying shock state,

results in the best outcomes.⁴ Definitive therapy depends on the cause of the shock state and may require additional diagnostic and therapeutic interventions. These efforts should be pursued in a timely manner, and, by necessity, may need to occur concurrently with resuscitative efforts. Finally, deviation from the expected clinical course and response to therapy should prompt a reassessment of the presumed cause of the shock state.

KEY POINTS

1. Circulatory shock is defined as a syndrome in which blood flow is inadequate to meet cellular metabolic requirements. The principal clinical manifestation of shock is that of organ hypoperfusion, which is most evident in the peripheral circulation, kidneys, and brain.
2. The development of shock is related to alterations in the major components of the circulatory system that regulate cardiovascular performance. These are intravascular volume, cardiac function, arteriolar resistance, capillary circulation, venules, venous capacitance circuit, and mainstream patency.
3. Circulatory performance can be assessed from the cardiac rate and rhythm, arterial blood pressure, cardiac filling pressures, cardiac output, and systemic vascular resistance. Although shock is frequently defined by hypotension, the level of arterial pressure is not a reliable indicator of circulatory performance and tissue perfusion.
4. Circulatory shock can be divided into four subsets: hypovolemic, cardiogenic, distributive, and obstructive. This classification can be simplified into two broad categories with typical hemodynamic profiles. The first category, hypodynamic shock, includes the hypovolemic, cardiogenic, and obstructive shock subsets. The second category, hyperdynamic shock, includes distributive shock. The central features of hypodynamic shock are a low cardiac output and vasoconstriction manifested by a high vascular resistance. Hyperdynamic circulatory shock is characterized by a high cardiac output and vasodilation manifested by a low vascular resistance.
5. The primary metabolic defect in circulatory shock is impaired oxidative metabolism. This impairment is most commonly caused by decreases in tissue oxygen supply owing to either global decreases in blood flow or maldistribution of blood flow. Cellular oxidative metabolism may also be impaired by mechanisms independent of tissue hypoperfusion. Accumulation of tissue CO₂ parallels the development of tissue hypoxia in circulatory shock.
6. Controversy exists over the optimal manner in which to monitor tissue perfusion in patients with circulatory shock. Commonly used variables such as heart rate, arterial pressure, and cardiac output correlate poorly with survival in critically ill patients. These observations have led to the use of indices of systemic oxygen metabolism as markers of tissue perfusion and the adequacy of resuscitative efforts.
7. The primary causes of organ dysfunction in circulatory shock are ischemic injury related to tissue hypoperfusion, mediator-related organ dysfunction, and reperfusion injury. The relative importance of these mechanisms varies with the cause of the shock state and the specific organ being examined.
8. The approach to patients with circulatory shock involves a rapid assessment of the underlying disease process and restoration of cardiopulmonary stability. The patient should be assessed for the etiology of the shock syndrome and evidence of organ hypoperfusion. Initial efforts to achieve cardiopulmonary stability should focus on ventilation, fluid infusion, and cardiac function. Restoration of systemic perfusion and definitive therapy directed at the etiology of the shock state should follow.

Circulatory failure is characterized by a decrease in cellular oxygen availability that is associated with a decrease in cellular partial pressure of oxygen (PO_2). When a critical PO_2 value is reached, oxidative phosphorylation is limited and leads to a shift from aerobic to anaerobic metabolism. The result is an increase in cellular and blood lactate concentrations associated with a decrease in adenosine triphosphate (ATP) synthesis. Adenosine diphosphate (ADP) and hydrogen ions accumulate and together with the elevated serum lactate levels leads to metabolic lactic acidosis. This state is called *dysoxia* and is accepted as a definition for “shock,” a state in which inadequate tissue oxygenation produces cellular injury. Shock often, but not always, results from a decrease in oxygen delivery (DO_2). A Task Force constituted by the European Society of Intensive Care Medicine has defined circulatory shock as a life-threatening, generalized form of acute circulatory failure associated with inadequate oxygen utilization by the cells.¹

Resuscitation from circulatory shock requires an emergency and global approach that is based on limited clinical features for establishing diagnosis and probabilistic therapy. The efficacy of this initial therapeutic strategy becomes part of the diagnostic approach: if the chosen therapy is successful, it retrospectively confirms the diagnosis. This initial diagnostic approach is essentially based on the physician's knowledge of global hemodynamics and oxygen-derived parameters. Rapidly available oxygen-derived biological markers can help with this process.

UNDERLYING PATHOPHYSIOLOGY OF GLOBAL FLOW AND OXYGEN DELIVERY

Addressing Global Adequacy of Tissue Oxygenation

Adequacy of tissue oxygenation is defined as an adapted oxygen supply (or DO_2) to oxygen demand.² Oxygen demand varies according to time and tissue type. Although oxygen demand cannot be measured or calculated, oxygen uptake or consumption ($\dot{V}O_2$) and DO_2 can both be quantified; they are linked by a simple relationship:

$$\dot{V}O_2 = DO_2 \times ERO_2$$

where ERO_2 represents the oxygen extraction ratio (ERO_2 in %; $\dot{V}O_2$ and DO_2 in mL O_2 /kg/min). DO_2 represents the total flow of oxygen in the arterial blood and is calculated as the product of cardiac output (\dot{Q}) and arterial oxygen content (CaO_2):

$$DO_2 = \dot{Q} \times CaO_2$$

with CaO_2 calculated as the product of hemoglobin (Hb, g/100 mL), arterial oxygen saturation (SaO_2 , %), and Hb O_2 capacity (1.39 mL O_2 /g Hb): $CaO_2 = Hb \times SaO_2 \times 1.39$.

Under physiologic control, oxygen demand equals $\dot{V}O_2$ (≈ 2.4 mL O_2 /kg/min for a 12 mL O_2 /kg/min DO_2 , which corresponds to a 20% ERO_2). The rate of oxygen delivered by blood is physiologically larger than that of $\dot{V}O_2$; DO_2 adapts to oxygen demand. When oxygen demand increases (e.g., during exercise), DO_2 adapts and increases.

During circulatory shock, as DO_2 declines secondary to a decrease in \dot{Q} and/or a decrease in CaO_2 , $\dot{V}O_2$ is maintained by a compensatory

increase in ERO_2 , $\dot{V}O_2$, and DO_2 , thus remaining independent. But as DO_2 decreases further, a critical point (DO_2 crit) is reached; ERO_2 can no longer compensate for the decrease in DO_2 , and at this critical level, $\dot{V}O_2$ becomes DO_2 dependent (Fig. 89-1). At this DO_2 crit (4 mL/kg/min), for a $\dot{V}O_2$ of about 2.4 mL/kg/min, ERO_2 reaches its critical point (ERO_2 crit) of 60%. When $\dot{V}O_2$ is higher, DO_2 crit is also higher. Increase in oxygen extraction occurs via two fundamental adaptive mechanisms³: (1) redistribution of blood flow among organs via an increase in sympathetic adrenergic tone and central vascular contraction (this is responsible for a decreased perfusion in organs with low ERO_2 , such as the skin and splanchnic area, and a maintained perfusion in organs with high ERO_2 , such as heart and brain) and (2) capillary recruitment within organs responsible for peripheral vasodilation (opposite to central vasoconstriction).

Using Mixed Venous Oxygen Saturation to Assess Adequacy of Global Tissue Oxygenation

In the clinical setting, mixed venous oxygen saturation (SvO_2) is used for assessing whole-body $\dot{V}O_2$ -to- DO_2 relationships. Indeed, according to the Fick equation, tissue $\dot{V}O_2$ is proportional to cardiac output:

$$\dot{V}O_2 = \text{cardiac output} \times (CaO_2 - CvO_2)$$

where CvO_2 is mixed venous blood oxygen content. To some extent, $\dot{V}O_2$ is approximately equal to cardiac output $\times (SaO_2 - SvO_2) \times Hb \times 1.39$, and SvO_2 is approximately equal to $SaO_2 - \dot{V}O_2 / (\dot{Q} \times Hb \times 1.39)$.

Four situations can be responsible for a decrease in SvO_2 : a decrease in SaO_2 (hypoxemia), Hb (anemia), cardiac output, or an increase in $\dot{V}O_2$ (like in exercise). At DO_2 crit, SvO_2 is about 40% (SvO_2 crit), with an ERO_2 of 60% and an SaO_2 of 100%. This SvO_2 crit has been identified in humans.⁴ It is important to emphasize that for the same decrease in CaO_2 (induced by a decrease in Hb or SaO_2), the decrease in SvO_2 will be more pronounced if cardiac output cannot adapt. Hence, SvO_2 represents the adequacy of global flow to the decrease in CaO_2 . A 40% SvO_2 is considered an imbalance between arterial blood oxygen supply and tissue oxygen demand with an evident risk of dysoxia. In the clinical setting, a decrease of SvO_2 of 5% from its normal value (77%-65%) is representative of a significant fall in DO_2 and/or an increase in oxygen demand (Fig. 89-2). If initial probabilistic treatment (fluid resuscitation, low-dose inotropes, and/or red blood cell transfusion) does not allow SvO_2 to be restored to a minimum of 65%, Hb, SaO_2 , and cardiac output should be individually measured to adapt to the appropriate treatment.

Assessing Global Flow

Global flow (i.e., cardiac output) is dependent on preload, myocardial contractility, afterload, and heart rate. Regional flow distribution is not homogeneous and is dependent on central and peripheral vascular tone, which ultimately results in composite systemic vascular resistances (SVR). As an oversimplification, mean arterial pressure (MAP) can be estimated as the product of cardiac output by SVR. When flow decreases, MAP remains stable and SVR increases; this corresponds to increased sympathetic adrenergic tone and central vascular contraction in low ERO_2 organs and preserved peripheral vasodilation in high ERO_2 organs. Overall, ERO_2 increases and SvO_2 decreases.

FIGURE 89-1 ■ O₂ uptake ($\dot{V}O_2$)-to-O₂ supply (DO₂) relationship.

When $\dot{V}O_2$ is supply independent ("independency"), following the relation $\dot{V}O_2 = y$, whole body O₂ needs are met. When $\dot{V}O_2$ becomes DO₂ dependent ("dependency"), according to the relation $\dot{V}O_2 = xDO_2$, $\dot{V}O_2$ starts to be linearly dependent on DO₂ at the critical DO₂ value (DO₂ crit), which corresponds to dysoxia (insufficient ATP synthesis as related to needs) and a shock state. DO₂ crit is influenced by global organism O₂ needs: when $\dot{V}O_2$ is decreased (e.g., by rest, sedation, hypothermia), the DO₂ crit is decreased as well (*lower dotted line; DO₂ crit[1]*); conversely, increased $\dot{V}O_2$ (e.g., by increased muscle activity, awakening, hyperthermia, sepsis) is associated with increased DO₂ crit (*upper dotted line; DO₂ crit[2]*).

Observation of inappropriate tissue perfusion (e.g., raised blood lactate level, metabolic acidosis, Svo₂ lower than 65%, decreased urinary flow) and its persistence despite probabilistic therapy (fluid, low-dose inotropes, red blood cells) should lead to optimizing flow according to the Frank-Starling curve. This can be assessed by invasive and noninvasive investigative procedures (see later).

During circulatory shock, $\dot{V}O_2$ -to-DO₂ dependency along with an increase in blood lactate levels implies oxygen debt. Several authors have reported that oxygen debt is related to the likelihood of multiple organ failure and mortality in postoperative or polytrauma patients.^{5,6} Patients who survive multiple organ failure have been shown to have a higher cardiac index, lower SVR, higher $\dot{V}O_2$, and higher Svo₂ than nonsurvivors.^{7,8} Rixen and Siegel⁶ demonstrated that the degree of tissue oxygen debt is related to an enhanced inflammatory response and associated with an increased risk of acute respiratory distress syndrome (ARDS) and higher mortality rates.

Several researches have emphasized the potential interest of using central venous oxygen saturation (Scvo₂) values for detecting global oxygenation impairment in experimental and clinical protocols.⁸⁻¹⁰ Furthermore, fluctuations between Svo₂ and Scvo₂ correlated relatively well, although absolute values differed.¹¹ Another important feature with Scvo₂ monitoring is that Scvo₂ can be continuously provided by central venous catheters equipped with optic fibers. In initial resuscitation of circulatory shock patients, insertion of a central venous catheter is a standard, rapid, and easy procedure.

In a landmark trial by Rivers et al., patients with septic shock were admitted to the emergency department and were randomized to either standard therapy (n = 133) or early goal-directed therapy (EGDT, n = 130) that targeted to achieve a central Scvo₂ of greater than 70%.¹² This study demonstrated a significant reduction in hospital mortality: 30.5% in the EGDT group compared with 46.5% in the standard therapy group (P = 0.009). An important point in this study was that 99.2% of patients receiving EGDT achieved their hemodynamic goals within the first 6 hours compared with 86% of those receiving standard therapy. This was the first study to demonstrate that early identification of patients with sepsis, associated with early initiation of GDT to achieve adequate tissue oxygenation by O₂ delivery (Scvo₂ monitoring), significantly improves mortality rates.¹² This study was further

FIGURE 89-2 ■ Venous O₂ saturation (SvO₂)-to-cardiac index (CI) relationship.

According to the modified Fick equation, the relationship SvO₂/CI is curvilinear. Subsequently, when O₂ uptake ($\dot{V}O_2$) is constant, CI variations lead to large variations in SvO₂ when the initial CI value is low. In contrast, when initial CI values are already high, CI variations do not influence SvO₂ very much. These relationships are modified when CI variations are associated with large modifications in $\dot{V}O_2$.

validated by more than ten following trials.¹³ However, recent studies with large sample sizes showed more conflicting results. The ProCESS trial in the United States,¹⁴ the ARISE trial in Australia and New Zealand,¹⁵ and the ProMISE trial in England¹⁶ showed that EGDT did not significantly improve mortality in patients with septic shock compared with usual care. This can largely be explained by the difference in population between the study of Rivers et al. and these three most recent studies. In 10 years, practices have been significantly influenced by the impact of the Surviving Sepsis Campaign, which also contained some of the findings from the Rivers et al. study.¹⁷ In these three recent studies, patients had Scvo₂ at baseline greater than 70%, which is a very different result from that observed by Rivers et al.

DECIDING DIAGNOSTIC AND TREATMENT STRATEGY

Treatment strategy starts with an early and rapid estimation of O₂ deficit, rapidly followed by an early probabilistic treatment (Fig. 89-3). The response to this early probabilistic treatment (modification of lactate, arterial pH, Scvo₂, or Svo₂) then suggests which complementary investigation should be conducted (e.g., echocardiography, esophageal Doppler, computed tomography [CT] scan) and which type of monitoring needs to be installed (e.g., invasive systolic arterial blood pressure variations, noninvasive or invasive assessment of cardiac output). These will help refine the diagnosis and optimize treatment.

Diagnosing Shock Type

Quantitative Shock (Decreased DO₂)

Decreased Flow (Hypovolemic, Cardiogenic, Obstructive). The leading causes of decreased flow are decreased circulatory volume (absolute or relative hypovolemia) and cardiac pump failure. An obstructive cause (like in massive pulmonary embolism, tamponade, or tension pneumothorax) is less common.

Hypovolemia is "absolute" after severe hydration defects, plasma, or blood loss; it can be "relative" when fluid administration is insufficient to compensate a loss in vascular tone in the context of sepsis or anaphylaxis (or use of large doses of sedative drugs). In that context, there is an inadequacy between the content (volume) and vascular capacity, and abnormal sympathetic tone is associated with altered capillary recruitment. Therefore, relative hypovolemia is often associated with altered redistribution of flow among and within organs. It is important to note that shock can result from a mixture of quantitative and distributive features and a mixture of absolute and relative hypovolemia.

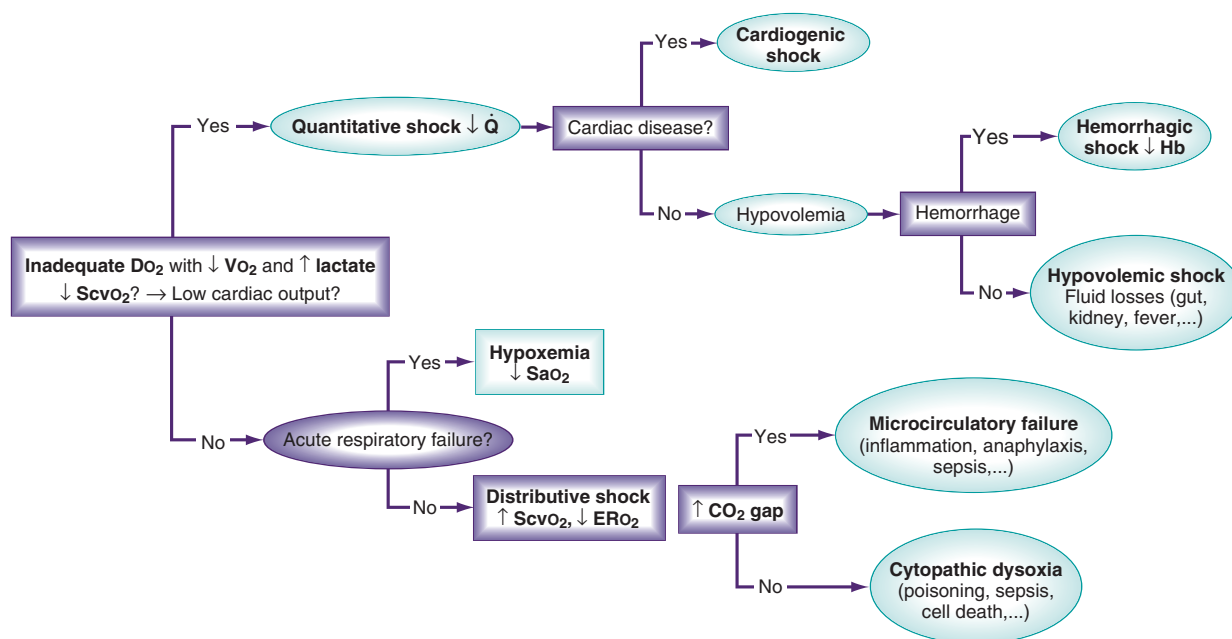

FIGURE 89-3 ■ Initial interpretation of a shock state. CO_2 gap, central venous-to-arterial CO_2 difference; DO_2 , O_2 supply; ERO_2 , oxygen extraction ratio; Hb, hemoglobin; Sao_2 , O_2 arterial saturation; Scvo_2 , central venous O_2 saturation; \dot{Q} , cardiac output; $\dot{\text{V}}\text{O}_2$, O_2 uptake.

Cardiac failure results from myogenic injury (infectious, viral, or ischemic disease), a major valvular disease, or a severe arrhythmia.

Decreased CaO_2 (Anemia, Hypoxemia, Poisoning). A decrease in Hb is not necessarily associated with hypovolemia. When associated with acute hemorrhage (hypovolemia), the decrease in DO_2 is magnified by the associated decrease in blood flow.

Hemoglobin capacity to carry O_2 can also be limited. During carbon monoxide poisoning, a decrease in DO_2 results from a loading competition on Hb between carbon monoxide and O_2 and is “maximized” by abnormal O_2 utilization (carbon monoxide interacts with oxidative phosphorylation) and a decrease in ERO_2 capabilities. In this particular case, shock is both quantitative and distributive.

In the presence of severe hypoxemia, because of an acute respiratory disorder, decreased Sao_2 leads to a decreased CaO_2 , and DO_2 that largely depends on an associated increase in cardiac output.

Distributive Shock (Decreased ERO_2)

This type of shock is linked to:

- Altered flow redistribution among organs secondary to inflammation, anaphylaxis, or some drugs (e.g., large doses of sedative agents)
- Decrease in capillary recruitment secondary to altered vascular reactivity, increased intravascular coagulation, increased blood cell adhesion, and/or endothelial edema
- Abnormal mitochondrial function (mitochondrial injury or dysfunction) described in “cytopathic hypoxia”¹⁸ or more precisely as cytopathic dysoxia, a situation in which cells cannot synthesize ATP, despite having sufficient global DO_2

Distributive shock may coexist with hypovolemic and/or cardiogenic shock. Because decreased ERO_2 is present, an elevated Svo_2 or Scvo_2 does not preclude that tissue hypoperfusion no longer exists. It is still possible to detect abnormalities in tissue perfusion through bedside microcirculatory exploration or by using the central venous-to-arterial carbon dioxide difference $\text{P}(\text{cv-a})\text{CO}_2$. In the latter, central venous PCO_2 is used as a surrogate for mixed venous PCO_2 .¹⁹ Central venous-to-arterial PCO_2 above 6 mm Hg can help in detecting septic shock patients who currently may remain inadequately resuscitated even though an Scvo_2 above 70% has been reached. In these patients, when compared to those who presented with a $\text{P}(\text{cv-a})\text{CO}_2$ below 6 mm

Hg, cardiac index was much smaller ($2.7 \pm 0.6 \text{ L/min/m}^2$ vs. $4.3 \pm 1.6 \text{ L/min/m}^2$), lactate concentration remained higher (7.5 ± 3.7 vs. $5.6 \pm 3.6 \text{ mmol/L}$), and organ failure score increases over a 24-hour time period. These results support the concept that hemodynamics requires further optimization in patients with impaired ERO_2 , and that targeting a $\text{P}(\text{cv-a})\text{CO}_2$ less than 6 mm Hg could be used as a complementary tool to do so (see Fig. 89-3). This was consistent with results found during abdominal surgery and in postoperative intensive care.^{20,21} In all studies, the threshold value was confirmed at around 6 mm Hg. $\text{P}(\text{cv-a})\text{CO}_2$ is associated with the arterial-venous oxygen content difference (Da-vO_2). The $\text{P}(\text{cv-a})\text{CO}_2/\text{Da-vO}_2$ ratio was proposed as a good monitoring variable in septic shock.²²

Choosing Appropriate Monitoring

Minimal monitoring consists of electrocardiography, pulse oximetry, and rapid arterial pressure recordings (every 5 minutes) and, soon after, a continuous and invasive recording (which facilitates the collection of arterial blood samples for blood gases and lactate levels). A central venous catheter allows measurement of central venous pressure, which often cannot help much in isolation (except when it remains lower than 5 mm Hg), but can help to guide fluid challenges. The central venous catheter facilitates infusion of drugs and fluids. It also allows for monitoring Scvo_2 , as discussed above.

Echocardiography cannot provide continuous hemodynamic data but allows for rapid identification of the type of hemodynamic disorder and has now been proposed as a first-line evaluation modality.²³ This information can be obtained rapidly even by physicians with minimal training (1- and 2-year training programs).²⁴ This is also the best modality to identify and characterize cardiac failure. In case of severe shock, where the patient is unresponsive to initial therapy, advanced hemodynamic monitoring is useful in identifying the key factors leading to hemodynamic abnormalities. Continuous or semi-continuous measurements of cardiac output and/or Svo_2 (or Scvo_2) as well as $\text{P}(\text{cv-a})\text{CO}_2$ are particularly useful to guide therapy and can also be nurse driven if strict medical protocols have been implemented.

A pulmonary artery catheter provides important hemodynamic variables including right atrial pressure (RAP), pulmonary artery

pressure (PAP), pulmonary artery occlusion pressure (PAOP), continuous cardiac output, and SvO₂ monitoring. Right atrial pressure and PAP is particularly useful in patients with right ventricular dysfunction. However, the data regarding the benefits from PAC in intensive care are conflicting. Former nonrandomized studies found an increased mortality and morbidity in patients monitored by PAC, but a meta-analysis of more than 5000 critically ill patients did not report any difference, in terms of safety and efficiency.²⁵

Transpulmonary thermodilution devices are somewhat less invasive than PAC. Continuous cardiac output measurement is provided by a combination of transpulmonary thermodilution and pulse contour analysis. A good agreement was reported with thermodilution cardiac output measured by PAC in unstable patients.²⁶ Beat-to-beat analysis improves the capacity to diagnose a decrease in cardiac output quickly and is more efficient in detecting short-term variations in cardiac output during therapeutic challenges. Transpulmonary thermodilution devices are able to assess extravascular lung water, a prognostic variable for mechanical ventilation weaning in patients with ARDS.²⁷ Therefore, in severe shock associated with ARDS, transpulmonary thermodilution devices may be useful.

Some devices are able to provide continuous cardiac output by pulse contour analysis without calibration. These are less invasive than PAC and transpulmonary thermodilution devices (they only need an artery catheter), but their reliability in terms of cardiac output in unstable patients, especially in septic shock, is still debated.^{28,29} More recently, noninvasive pulse contour analysis methods have been developed but are not reliable in patients in circulatory shock.³⁰ All these devices provide dynamic preload-dependency indices that are useful to guide fluid challenges.³¹ However, several events (arrhythmia, tidal volume less than 7 mL/kg⁻¹) limit this kind of evaluation.

Bioreactance is a noninvasive technique to assess cardiac output but is not reliable in critically ill patients.³² Transesophageal Doppler is a valuable technique to assess cardiac output but requires frequent replacement of the probe that is not suitable in most ICU patients; it is more adequate in the operating room.

Iterative blood gas analysis (another approach justifying insertion of an arterial line), metabolic acidosis and lactate concentration evaluation, are other ways to assess global tissue oxygenation and to complement ScvO₂ or SvO₂ measurements.

THERAPEUTIC PRINCIPLES: SYMPTOMATIC AND ETIOLOGIC TREATMENTS

Symptomatic Treatment

Emergency therapeutic principles of care need to be decided at the time the initial diagnostic strategy is considered. It is necessary to give supplemental O₂ and ventilatory support in response to acute respiratory failure either through a face mask or by endotracheal intubation. Acute circulatory failure is treated by initial fluid loading in the absence of left ventricular failure (see later). If decreased global contractility is present, inotropic support is considered. In case of anaphylactic shock, emergency treatment includes intravenous epinephrine to treat allergy-induced vasodilation.

Fluid loading is the first step in the treatment, and its first goal is to optimize left ventricular preload to improve Do₂ by increasing cardiac output.³³ There is, however, an associated risk of interstitial edema—in particular, pulmonary edema. Unless the patient has an acute lung injury, fluid loading aims at maximizing cardiac output³³ according to the Frank-Starling relationship, decreased lung gas exchange being detected by a decrease in SaO₂ (or by a decrease in its surrogate, pulse oximetry). When applicable, dynamic preload-dependency indices (arterial pulse pressure variations) should be preferred to static indices to guide fluid loading.³¹ Absolute value of CVP or PAOP should not be used alone to guide fluid therapy. Fluid administration should be titrated cautiously (except in severe hemor-

rhage) as fluid challenge. Of course, if cardiac output is monitored, stroke volume variations during fluid challenge must also be considered when applicable.

Normalization of hemoglobin concentration (Hb), by red blood cell transfusion is not required. Threshold values of 7 g/dL resulted in similar outcomes as higher thresholds in several randomized studies,^{34,35} but caution should be advised in patients with recent myocardial ischemia and high risk of coronary disease and in patients under extracorporeal life support (ECLS). In all cases, targeting an ScvO₂ larger than 70% may be a helpful guide for transfusion.³⁶

Catecholamines help in restoring perfusion pressure and maintaining cardiac output, thus allowing sufficient Do₂; this should allow regional flow distribution and improved ERO₂. All catecholamines are inotropes; they can be divided into (1) inodilators when they combine inotropic and vasodilatory properties (low-dose dopamine, any dose of dobutamine or dopexamine) or (2) inoconstrictors when they combine inotropic and vasoconstricting properties (high-dose dopamine, any dose of epinephrine or norepinephrine). Inodilators increase flow; inoconstrictors increase perfusion pressure. Because of variable individual sensitivity to catecholamines, dose titration is necessary.³⁷ More potent vasopressors such as vasopressin have been tested with conflicting results, in particular with regard to regional circulation. In a large multicenter, randomized, double-blind trial, vasopressin showed no benefit as a first-line vasopressor compared to norepinephrine in septic shock.³⁸ It is important to emphasize that a rise in blood pressure may not be a surrogate for clinical benefit. Indeed, in a large placebo-controlled clinical trial, administration of the nonselective nitric oxide inhibitor, N^G-methyl-L-arginine, during septic shock produced both significant increases in blood pressure and significant increases in mortality.³⁹

Some evidence exists to guide selection of the threshold for blood pressure maintenance. A MAP around 65 mm Hg is sufficient in most patients with septic shock.⁴⁰ However, in patients with a history of hypertension, a higher MAP is associated with a lower incidence of acute kidney injury.⁴⁰ Lower threshold is tolerated in severe bleeding without acute brain injury. Because increasing blood pressure through vasoconstriction may be associated with a decrease in flow, a tradeoff may exist between raising blood pressure and decreasing cardiac index that will vary depending on the specific vasopressor or combined inotrope/vasopressor.³⁷

Inotropic support should be considered in case of cardiac failure associated with impaired organ perfusion (low SvO₂, increased blood lactate level, high P(cv-a)CO₂, acute kidney injury), but not just facing a decrease in left ventricular ejection fraction. In case of refractory cardiac failure, ECLS should be considered, especially in case of primary cardiogenic shock (congenital or postischemic), postcardiotomy cardiogenic shock, and right ventricular failure associated with ARDS or massive pulmonary embolism.

Applying such principles for symptomatic treatment in septic shock patients has resulted in improving mortality. The longer a site was involved in a Surviving Sepsis Campaign program, the greater was the benefit. In a 7.5-year study, mortality rates dropped 0.7% per site for every 3 months of participation. Length of hospital and ICU stay decreased by 4% (95% CI, 1%-7%) for every 10% increase in site compliance with the Surviving Sepsis Campaign bundle.¹⁷

Other Therapeutic Principles

The importance of correction of metabolic acidosis and the use of intravenous bicarbonate for shock-induced anion gap acidosis has been overemphasized in the past. Indeed, clinical studies, including one randomized, prospective trial, failed to show any hemodynamic benefit from bicarbonate therapy either to increase cardiac output or to decrease vasopressor requirements, regardless of the degree of acidemia. Cardiac function does not appear to be significantly decreased when the arterial pH remains higher than 7.00. Bicarbonate infusion, apart from renal or digestive losses, is therefore not recommended, unless the patient has hyperkalemia.⁴¹

In patients with septic shock, stress-dose (low-dose) steroid therapy (hydrocortisone 200 mg/day) needs to be considered, especially if the decrease in blood pressure requires high or increasing concentrations of vasopressors, once appropriate antibiotics are being given or the infectious site is controlled.³³ Steroid therapy may be weaned once vasopressors are no longer required. Beyond 72 hours, absence of any hemodynamic improvement suggests that the hydrocortisone treatment is futile.

Although not oriented toward better circulatory efficacy, a number of treatments are essential in septic shock.³³ Control of the infectious source is essential. Empiric or probabilistic antibiotics must be directed against gram-negative microorganisms and potentially resistant pathogens. This justifies double or sometimes triple antibiotherapy. It theoretically offers the following advantages: widening the spectrum of activity, antibacterial synergy, increased bactericidal speed, and decreased risk for emergent resistant germs.

PROGNOSIS

The main prognostic factors for circulatory shock are the number of organ failures present on admission, delay in starting treatment, and response to symptomatic treatment. In cases of septic shock, control of the infectious source and the appropriate antibiotic therapy are essential prognostic factors. The early timing of GDT certainly influences the severity of multiple organ failure and the prognosis.

Dellinger RP, Levy MM, Carlet JM, et al. Surviving Sepsis Campaign: international guidelines for management of severe sepsis and septic shock: 2008. *Intensive Care Med* 2008;34:17–60.

The objective of the Surviving Sepsis Campaign, an international effort to increase awareness and improve outcome in patients with severe sepsis, was to develop management guidelines for severe sepsis and septic shock that would be of practical use for the bedside clinician. The process included a modified Delphi method, a consensus conference, several subsequent smaller meetings of subgroups and key individuals, teleconferences, and electronic-based discussion among subgroups and among the entire committee. Evidence-based recommendations, with their renewal in 2008, were made in 2004 regarding many aspects of the acute management of sepsis and septic shock that will hopefully translate into improved outcomes for the critically ill patient. The impact of these guidelines was formally tested and published in 2010 (see below).

Levy MM, Dellinger RP, Townsend SR, et al. The Surviving Sepsis Campaign: results of an international guideline-based performance improvement program targeting severe sepsis. *Intensive Care Med* 2010;36:222–231.

The Surviving Sepsis Campaign (SSC or “the Campaign”) developed guidelines for management of severe sepsis and septic shock. A performance improvement initiative targeted changing clinical behavior (process improvement) via bundles based on key SSC guideline recommendations on process improvement and patient outcomes. A multifaceted intervention to facilitate compliance with selected guideline recommendations in the ICU, emergency departments, and wards of individual hospitals and regional hospital networks was implemented voluntarily in the United States, Europe, and South America. Elements of the guidelines were “bundled” into two sets of targets to be completed within 6 hours and within 24 hours. The Campaign was associated with sustained, continuous quality improvement in sepsis care. Although not necessarily cause and effect, a reduction in reported hospital mortality rates was associated with participation. Data from 15,022 subjects at 165 sites (included from January 2005 through March 2008) were analyzed to determine the compliance with bundle targets and association with hospital mortality. Compliance with the entire resuscitation bundle increased linearly from 10.9% in the first site quarter to 31.3% by the end of 2 years ($P < 0.0001$). Compliance with the entire management bundle started at 18.4% in the first quarter and increased to 36.1% by the end of 2 years ($P = 0.008$). Unadjusted hospital mortality decreased from 37% to 30.8% over 2 years ($P = 0.001$). The adjusted odds ratio for mortality improved the longer a site was in the Campaign, resulting in an adjusted absolute drop of 0.8% per quarter and 5.4% over 2 years (95% CI, 2.5%–8.4%).

KEY POINTS

1. Circulatory shock occurs when a critical cellular partial pressure of oxygen (PO_2) is reached, a state at which inadequate tissue PO_2 produces cell dysoxia (cell oxygen consumption and ATP production are oxygen-limited) and injury.
2. Shock often, but not always, results from a decreased oxygen delivery (DO_2).
3. Initial resuscitation from circulatory shock consists of (1) addressing the global adequacy of tissue oxygenation, (2) assessing the global flow, (3) diagnosing the shock type, and (4) deciding the best probabilistic treatment.
4. Treatment aims at (1) reducing preload dependency, (2) restoring cardiac contractility, (3) improving perfusion pressure, (4) reaching oxygen supply-to-oxygen needs independency, and (5) eliminating disease sources (e.g., anaphylaxis, infection, myocardial ischemia).

Michard F, Boussat S, Chemla D, et al. Relation between respiratory changes in arterial pulse pressure and fluid responsiveness in septic patients with acute circulatory failure. *Am J Respir Crit Care Med* 2000;162:134–138.

In mechanically ventilated patients with acute circulatory failure related to sepsis, the authors investigated whether the respiratory changes in arterial pulse pressure (ΔPP) could be related to the effects of volume expansion (VE) on cardiac index. It was concluded that in that particular population of patients, analysis of ΔPP is a simple method for predicting and assessing the hemodynamic effects of VE.

Rivers E, Nguyen B, Havstad S, et al. Early goal-directed therapy in the treatment of severe sepsis and septic shock. *N Engl J Med* 2001;345:1368–1377.

Goal-directed therapy involves adjustments of cardiac preload, afterload, and contractility to balance oxygen delivery with oxygen demand. The purpose of this study was to evaluate the efficacy of early goal-directed therapy before admission to the ICU. Early goal-directed therapy provided significant benefits with respect to outcome in patients with severe sepsis and septic shock.

Vallée F, Vallet B, Mathe O, et al. Central venous-to-arterial carbon dioxide difference: an additional target for goal-directed therapy in septic shock? *Intensive Care Med* 2008;34:2218–2225.

This study tested the hypothesis that, in resuscitated septic shock patients, central venous-to-arterial carbon dioxide difference [$P(cv-a)CO_2$] may serve as a global index of tissue perfusion when the central venous oxygen saturation ($Scvo_2$) goal value has already been reached. In a prospective observational study, 50 consecutive septic shock patients with $Scvo_2 > 70\%$ were included immediately after their admission into the ICU (T0) following early resuscitation in the emergency unit. Patients were separated in Low $P(cv-a)CO_2$ group (Low gap; $n = 26$) and High $P(cv-a)CO_2$ group (High gap; $n = 24$) according to a threshold of 6 mm Hg at T0. Measurements were performed every 6 hours over 12 hours (T0, T6, T12). At T0, there was a significant difference between Low-gap patients and High-gap patients for cardiac index (4.3 ± 1.6 vs. 2.7 ± 0.8 L/min/m², $P < 0.0001$) but not for $Scvo_2$ values (78 ± 5 vs. $75 \pm 5\%$, $P = 0.07$). From T0 to T12, the clearance of lactate was significantly larger for the Low-gap group than for the High-gap group ($P < 0.05$), as well as the decrease of SOFA score after 24 hours ($P < 0.01$). At T0, T6, and T12, cardiac index and $P(cv-a)CO_2$ values were inversely correlated ($P < 0.0001$). Therefore, when the 70% $Scvo_2$ goal is reached, the presence of a $P(cv-a)CO_2 > 6$ mm Hg might serve as a useful tool to identify patients who remain inadequately resuscitated.

RATIONALE FOR USING INOTROPIC THERAPY IN THE CRITICALLY ILL

Two different objectives for using inotropes in the critically ill have been considered: (1) the attempt to improve cardiac function in patients with low blood flow related to reduced myocardial contractility and (2) the attempt to achieve supranormal values of cardiac output in order to prevent or reduce oxygen debt; in this situation, inotropes might be given after volume resuscitation, even in the absence of formally documented myocardial depression.

Use of Inotropes for Reversing Impaired Myocardial Contractility

The first category of situations where inotropic therapy is generally considered includes cardiogenic shock, acute heart failure, or acute exacerbation of chronic heart failure. However, although the use of such therapy in these clinical conditions seems logical on a classic pathophysiologic basis, no demonstration of a beneficial impact on morbidity and mortality can be found in the literature. Moreover, almost all the commercially available inotropes have been shown to be associated with an increased mortality rate when given on a long-term basis to patients with chronic heart failure. It has been postulated that the long-term use of inotropes leads to the deterioration of left ventricular function through the acceleration of myocardial cell apoptosis.¹ Additionally, the beneficial effects on the mortality rate with agents known to have negative inotropic effects such as beta-blockers is now well established in patients with chronic heart failure with preserved ejection fraction² or reduced ejection fraction.³ Therefore, inotropic therapy is generally reserved for patients with cardiogenic shock or those with advanced heart failure whose condition is refractory to standard therapy including diuretics, digoxin, beta-blockers, and angiotensin-converting enzyme inhibitors. Under these conditions, clinicians can expect short-term positive effects of intravenous inotropic therapy allowing cardiovascular stabilization. This therapy can also be used in patients with refractory heart failure who are waiting for mechanical circulatory support (left ventricular assist devices, extracorporeal membrane oxygenation) and/or cardiac transplantation. In those with potentially reversible causes of acute heart failure (such as myocardial infarction or acute myocarditis), short-term inotropic therapy must be considered as an appropriate bridge to coronary revascularization or recovery. The development of bedside echocardiography in the intensive care unit (ICU) should allow the appropriate use of inotropic therapy since this method provides a more accurate assessment of systolic cardiac function than traditional invasive methods as pulmonary artery catheterization.

Use of Inotropes for Achieving Supranormal Levels of Oxygen Delivery or for Being Incorporated in a Goal-Directed Therapeutic Approach

High-Risk Surgical Patients

The concept of attempting to achieve supranormal hemodynamic endpoints emerged from studies in high-risk surgical patients. In a

prospective study in high-risk patients undergoing surgery, Shoemaker et al. showed that the use of supranormal hemodynamic values as therapeutic endpoints was associated with a reduction in mortality rate from 33% to 4%.⁴ In the protocol group, dobutamine and dopamine were given as inotropic drugs, even in the absence of evidence of reduced cardiac contractility, when volume resuscitation (and packed red blood cells, if necessary) failed to achieve supranormal values of oxygen delivery⁴ (>600 mL/min/m²). Thereafter, some debate concerning the perioperative fluid management strategy has emerged, especially during abdominal surgery. On the one hand, restricted perioperative fluid management could decrease the rate of postoperative complications and promote faster recovery.⁵⁻⁷ On the other hand, randomized trials did not confirm the supposed benefits of fluid restriction on recovery after elective surgery.^{8,9} Excessive fluid restriction could lead to hypovolemia and more postoperative complications as anastomotic leaks and sepsis.¹⁰

In fact, the most important point was not the use of the perioperative fluid strategy itself but rather the use of a goal-directed strategy based on stroke volume,¹¹⁻¹³ oxygen delivery index,^{14,15} or cardiac index.¹⁶ In these randomized studies, the volume of intraoperative fluids was decreased,^{14,15} unchanged,¹⁶ or increased.¹¹⁻¹³ Nevertheless, in all these studies, postoperative complications or hospital length of stay was decreased. Two reviews confirmed that a deliberate perioperative increase in oxygen delivery above supranormal values using fluid infusion and various inotropic drugs (dobutamine, dopamine, epinephrine, dopexamine) in high-risk patients undergoing surgery was associated with a decreased mortality rate and postoperative complications.^{17,18} It is important to emphasize that (1) benefits are most pronounced in patients receiving fluid and inotropic therapy as opposed to fluids alone to achieve supranormal values of cardiac index or oxygen delivery with the use of minimally invasive cardiac output monitors,¹⁹ (2) benefits related to the use of an intraoperative goal-directed therapy could also concern low- and moderate-risk patients,²⁰ and (3) such an early goal-directed therapy (EGDT) is not considered after complications have already developed.¹⁸ However, more recently, the interest of perioperative goal-directed therapy has been questioned.^{21,22} In a pragmatic, multicenter randomized trial in high-risk patients undergoing major gastrointestinal surgery, Pearse et al. assessed the clinical effectiveness of a deliberate perioperative strategy including fluid administration and dopexamine to achieve and maintain a maximal stroke volume.²² When compared to usual care, goal-directed therapy was not associated with a significant reduction in moderate or major postoperative complications.²² Nevertheless, after incorporating these results into an updated systematic review and metaanalysis, the deliberate perioperative strategy was associated with a significant reduction in the percentage of patients who developed postoperative complications.²² It is important to note that in the group of usual care, fluid administration was based on central venous pressures and could be considered, in part, as goal-directed therapy.²² It remains unclear, however, whether potential benefits could be related to the increased oxygen delivery per se or other antiinflammatory effects of catecholamines.²³ In this regard, it has been demonstrated that the increased oxygen delivery per se improved microvascular flow and tissue oxygenation.²⁴ Nevertheless, an experimental study of murine septic shock has shown that dopexamine infusion per se reduces the systemic inflammatory response, attenuates leukocyte infiltration, and prevents hepatic and renal injury at doses that have no effects on global or

regional hemodynamics.²⁵ The issue of drug dosage is also essential. A recent metaanalysis has suggested that in the setting of major surgery, dopexamine at low doses, but not at high doses, improves outcome.²⁶ From all these findings, it is still reasonable to consider the increase in cardiac output and oxygen delivery toward supranormal values during the perioperative period in high-risk patients undergoing elective major surgery.

Critically Ill Patients

It is debatable whether a supranormal hemodynamic target approach can be applied to patients admitted to the ICU for acute illnesses. On the one hand, a pathologic oxygen consumption/supply dependency, presumably due to impaired oxygen extraction capacities, has been reported in various categories of acute illnesses such as sepsis²⁷ and acute respiratory distress syndrome.²⁸ Such a phenomenon was reported to correlate with the presence of increased blood lactate, to be a marker of global tissue hypoxia,²⁷ and to be associated with a poor outcome.²⁹ This so-called pathologic oxygen consumption/supply dependency would incite the clinician to increase oxygen delivery toward supranormal values to overpass its critical level. However, such an aggressive therapeutic approach has been seriously questioned since the publication of randomized clinical trials performed in patients with acute illnesses and who did not demonstrate any benefit from the deliberate manipulation of hemodynamic variables toward values higher than physiologic values.^{30,31} In one of these studies, the mortality rate was higher in the group of patients assigned to receive an aggressive treatment aimed at achieving supranormal values of oxygen delivery.³⁰ It was postulated that the deleterious consequences of the use of high doses of dobutamine in patients in the protocol group were responsible for the increased mortality rate. It should be noted that (1) the patients in the protocol group received high doses of the inotropic agent despite no evidence of any deficit of inotropic function and that (2), in most of these patients, the aggressive inotropic support failed to achieve the target value of oxygen consumption (170 mL/min/m^2). The later analysis of the subgroup of septic patients in a study showed that survivors were characterized by their ability to increase both oxygen delivery and oxygen consumption, regardless of their group of randomization.³² Nonsurviving patients were characterized by their inability to increase oxygen consumption despite the increase in oxygen delivery, suggesting a more marked impairment of peripheral oxygen extraction in nonsurvivors than in survivors.³² In addition, the ability to increase cardiac output and oxygen delivery was also significantly reduced in nonsurvivors than in survivors, suggesting a decrease in cardiac reserve in patients who will die.³² This is not a surprising finding since the degree of myocardial dysfunction in septic shock correlates with an increased risk of death. In this regard, it has been suggested that the response to a dobutamine challenge has a prognostic value in septic patients since in two prospective studies survivors were able to increase both oxygen consumption and oxygen delivery in response to dobutamine, while nonsurvivors were unable to increase either oxygen delivery or oxygen consumption or both.^{33,34}

Data from all the results of randomized controlled studies indicate that a deliberative attempt to achieve supranormal hemodynamic targets in the general population of critically ill patients is no longer recommended.^{35,36} However, in the early phase of septic shock with low blood flow and oxygen delivery, an aggressive hemodynamic therapy, including inotropes, aimed at rapidly normalizing the central venous oxygen saturation (ScvO_2) as a surrogate of oxygen delivery, was demonstrated to result in a better outcome in a monocenter randomized controlled trial.³⁷ This result has led to the popularity of the concept of EGDT with ScvO_2 as the main hemodynamic target. Nevertheless, three recent multicenter randomized studies have shown that EGDT using ScvO_2 did not reduce all-cause mortality,³⁸⁻⁴⁰ duration of organ support, or hospital length of stay.^{38,40} However, compared to the study by Rivers et al.,³⁷ patients were fluid resuscitated before randomization, such that the average baseline ScvO_2 was already higher than 70% (the target of the EGDT arm). Such a fact

certainly accounted for the absence of superiority of EGDT over the control arms in these studies.³⁸⁻⁴⁰ This clearly cannot rule out the strategy of increasing oxygen delivery and targeting ScvO_2 higher than 70% when ScvO_2 is lower than 70% as this was the case in majority of the patients in the study by Rivers et al.³⁷ Thus, in the early phase of septic shock and maybe in other acute illnesses, it could be essential to rapidly restore normal global blood flow conditions to avoid further deleterious consequences of systemic hypoperfusion. In later stages of the disease, with inflammatory processes and organ dysfunction already developed, no evidence of benefit from a further increase in oxygen delivery has been shown in the literature. Nevertheless, it seems likely that cardiac output should be kept in the normal range by using fluids and/or inotropes to prevent worsening of the insult. It should be stressed that even in the EGDT approach, their use should not only be based on ScvO_2 but also on the presence of established cardiac dysfunction, which is at best diagnosed on echocardiography³⁶ and after checking that hypovolemia and hypotension have been already corrected.

PHARMACOLOGIC PROPERTIES OF INOTROPIC AGENTS

Different inotropic drugs are available. Some of them act on adrenergic receptors located at the surface of the cardiomyocytes, while others exert their effects into the myocardial cell.

Adrenergic Signaling

Natural as well as synthetic catecholamines increase the Ca^{2+} cytosolic concentration, which is directly related to the force of contraction (Fig. 90-1). Ca^{2+} fixes on the troponin C Ca^{2+} -specific binding site, inducing a conformational change that leads to the fixation of the myosin head to the actin filament. Hydrolysis of the adenosine triphosphate (ATP)

FIGURE 90-1 ■ Mechanisms of action of inotropic agents at the cellular level. Schematic representation. Beta-agonist agents fix the beta receptor and stimulate the formation of cyclic AMP (cAMP) from AMP through adenylate cyclase. Cyclic AMP activates protein kinase A (PKA), which provokes the extrusion of Ca^{2+} from the sarcoplasmic reticulum into the cytosol through phosphorylated ryanodine receptors. Ca^{2+} fixes troponin C (Tnc) and finally activates the fixation of actin on myosin filaments. Phosphodiesterase (PDE) inhibitors also increase the cAMP concentration by inhibiting its degradation. Ca^{2+} sensitizers increase inotropism through the enhancement of troponin C sensitivity for Ca^{2+} . Cardiac myosin activators increase the activity of the ATPase of the myofibrils, increasing the contractile force of the cardiomyocytes without increasing the amount of ATP molecules required for contraction. Istaroxime inhibits Na^+/K^+ ATPase, increasing the activity of the sarcoplasmic reticulum Ca^{2+} ATPase pump and increasing the reuptake of Ca^{2+} by the sarcoplasmic reticulum.

molecule located on the myosin head to adenosine diphosphate (ADP) simultaneously induces the flexion of the myosin neck and the shortening of the contractile apparatus.

A rapid overview of the physiologic response to adrenergic receptor stimulation is essential to understand the pharmacologic properties of these drugs. Receptors of the adrenergic system are classed as α_1 , α_2 , β_1 , β_2 , and dopaminergic receptors. Activation of the β_1 receptors and, to a lesser degree, the α_1 receptors, is responsible for the inotropic effect of adrenergic agents.

Beta1-Adrenergic Receptors

Beta-adrenergic receptors are transmembrane proteins located in the sarcolemma. The β_1 receptor subtype is mainly represented in the human heart. Its stimulation induces inotropic, lusitropic, chronotropic, and dromotropic effects that result from the enhancement in Ca^{2+} cytosolic concentration. Binding of a β_1 -agonist agent to its receptor stimulates the Gs protein. Guanosine diphosphate, normally fixed to the stimulatory α_s subunit of the Gs protein, is replaced by guanosine triphosphate, and the α_s -guanosine triphosphate complex binds to adenyl cyclase, which then becomes activated. Cyclic adenosine monophosphate (cAMP) is formed from ATP and activates protein kinase A. Protein kinase A phosphorylates and activates several cellular structures as follows:

- The ryanodine receptors of the sarcoplasmic reticulum, leading to the enhanced extrusion of Ca^{2+} out of the sarcoplasmic reticulum. Indeed, the main part of the Ca^{2+} cytosolic content needed for contraction is provided by the sarcoplasmic Ca^{2+} store. The entry of Ca^{2+} through the membrane L-type channels modifies the molecular conformation of the ryanodine receptor of the sarcoplasmic reticulum. Parts of these ryanodine receptors are Ca^{2+} channels that enable the massive release of Ca^{2+} out of the sarcoplasmic reticulum (see Fig. 90-1).
- The sarcolemmal L-type Ca^{2+} channels, increasing their opening time. This leads to an increased amount of cytosolic Ca^{2+} available for sarcoplasmic reticulum Ca^{2+} release and for contraction. The increase in intracytosolic Ca^{2+} concentration also leads to the activation of calmodulin. This ubiquitous protein enables the phosphorylation of other proteins once it has fixed Ca^{2+} .
- The myosin light chain through the myosin light chain ATPase. This phosphorylation enhances the responsiveness of the cardiac contractile protein to Ca^{2+} and helps increase the affinity of myosin for actin, thus participating in the inotropic effect.
- The phospholamban and the sarcolemmal $\text{Na}^+/\text{Ca}^{2+}$ exchanger, leading to a faster decrease in Ca^{2+} cytosolic concentration after contraction and accounting for the lusitropic effect. Indeed, relaxation is dependent of Ca^{2+} reuptake by the sarcoplasmic reticulum through the sarcoendoplasmic reticulum Ca^{2+} ATPase pump. The activity of sarcoendoplasmic reticulum Ca^{2+} ATPase is normally inhibited by phospholamban located in the sarcoplasmic reticulum membrane near the Ca^{2+} pump. The phosphorylation of phospholamban relieves this inhibition, and Ca^{2+} uptake by the sarcoplasmic reticulum is thus stimulated.

Beta2-Adrenergic Receptors

The β_2 receptor subtype is mainly represented in noncardiac structures. Beta2-adrenergic stimulation induces arterial and venous relaxation. The effects of β_2 stimulation in vascular smooth muscle result from a different activation pathway: once the Ca^{2+} intracytosolic concentration increases, it fixes the calmodulin regulatory protein, and the Ca^{2+} -calmodulin complex activates the myosin light chain kinase, leading to the inhibition of phosphorylation of the myosin light chain and finally smooth muscle relaxation.

Alpha-Adrenergic Receptors

When an agonist fixes the α_1 -receptor, Gh, which is one of the G-protein family, stimulates phospholipase C, which splits phosphatidyl inositol into inositol triphosphate and 1,2-diacylglycerol. Inositol triphosphate stimulates the release of Ca^{2+} from the sarcoplasmic

reticulum. Alpha2-adrenoreceptor stimulation inhibits adenylate cyclase and reduces cAMP intracellular concentration. Alpha adrenoreceptors are not prominent in the cardiac tissue but are in the vascular wall. Cardiac α_1 -stimulation induces a positive inotropic effect; α_1 and α_2 stimulations induce potent arterial and venous constriction.

Pharmacologic Properties of Inotropic Agents Used in Clinical Practice

Epinephrine

Epinephrine is the main physiologic adrenergic hormone of the adrenal medullary gland. It is a potent stimulator of α , β_1 , and β_2 receptors. The α -adrenergic effect is responsible for a marked arterial and venous vasoconstriction. Epinephrine increases systolic arterial pressure, but its effect on vasculature is partly counteracted by β_2 -mediated vasodilation. Diastolic blood pressure is thus only slightly affected by epinephrine, and the increase in mean arterial pressure (MAP) is less than that with norepinephrine.

Through cardiac β_1 stimulation, epinephrine increases heart rate and inotropism. The effects of the combination of the latter, along with the α -mediated venous constriction promoting venous return and cardiac preload, results in an increase in cardiac output. Epinephrine also facilitates ventricular relaxation and enhanced coronary blood flow through the increase in myocardial oxygen consumption.

Norepinephrine

Norepinephrine is the physiologic mediator released by the postganglionic adrenergic nerves. It is a potent α - and β_1 -adrenergic agonist, but it has little activity on β_2 receptors. Through its α -adrenergic effect, norepinephrine induces potent arterial and venous constriction. It increases systolic as well as diastolic blood pressure, left ventricular afterload, and cardiac filling pressures. Its α -adrenergic effect also induces the reduction of peripheral venous capacitance and thus results in decreased unstressed venous blood volume and increased stressed venous blood volume. This is responsible for increased mean systemic filling pressure, venous return pressure gradient, and venous return.^{41,42} β_1 stimulation results in a positive inotropic effect and an increase in stroke volume. However, the chronotropic effect is counteracted by baroreflex stimulation following vasoconstriction. Consequently, the heart rate is unchanged or reduced, and the cardiac output can be unchanged. The coronary blood flow is enhanced by norepinephrine because of coronary vasodilation secondary to enhanced cardiac metabolism and the normalization of diastolic blood pressure when low.

Dopamine

Dopamine is the immediate physiologic precursor of norepinephrine and epinephrine. The cardiovascular effects of dopamine are mediated by several types of receptors that are activated at different dopamine concentrations and by norepinephrine produced by the transformation of dopamine.

At low rates of administration ($<5 \mu\text{g/kg/min}$), dopamine activates D1 receptors located in renal, mesenteric, cerebral, and coronary vessels and induces vasodilation without affecting arterial blood pressure. At higher and intermediate rates of administration ($5\text{--}10 \mu\text{g/kg/min}$), dopamine predominantly stimulates the β_1 -adrenergic receptor and thus enhances inotropism and increases heart rate. At such rates of infusion, dopamine increases systolic blood pressure without altering diastolic blood pressure because stroke volume is enhanced and arterial vascular tone is only slightly altered. Norepinephrine resulting from dopamine transformation contributes to these cardiovascular effects. At higher rates of administration ($10\text{--}20 \mu\text{g/kg/min}$), dopamine predominantly activates vascular α_1 -adrenergic receptors and induces arterial and venous vasoconstriction, counteracting D1-receptor-mediated vasodilation. This vasoconstriction increases arterial blood pressure, venous return, and cardiac filling pressures. At higher rates of administration, the hemodynamic effects of dopamine are similar to those of norepinephrine.

Dobutamine

Dobutamine is a synthetic adrenergic agonist derived from dopamine. Its effects on adrenergic receptors are complex but do not result from endogenous transformation to norepinephrine. Dobutamine simultaneously activates different adrenergic receptors with some opposite effects. In fact, the clinically used drug is a racemic mixture of a (–) enantiomer, activating α_1 -adrenergic receptors, and of a (+) enantiomer, activating β_1 and β_2 receptors. The α_1 - and β_1 -adrenergic stimulation results in inotropic and chronotropic effects. Dobutamine does not exert any intrinsic vascular effect because the vasoconstriction induced by α_1 stimulation is counteracted by the β_2 vasodilating effect.

Dopexamine

Dopexamine is a synthetic catecholamine inducing β_2 - and dopaminergic-receptor activation, with no effect on α -adrenergic receptors and a weak direct effect on β_1 -adrenergic receptors. It also exerts indirect effects through the inhibition of the neuronal reuptake of norepinephrine. Its administration induces vasodilation and the inotropic effect with substantially increased stroke volume.

Isoproterenol

Isoproterenol (or isoprenaline) is a potent synthetic β -adrenergic agonist with a very low affinity for α -adrenergic receptors. Through its potent β_2 vasodilating effect, it induces a fall in diastolic and mean blood pressure, whereas the systolic blood pressure is increased owing to the increase in stroke volume related to its β_1 -adrenergic activation. The combination of the latter effect and the marked increase in heart rate leads to an enhanced cardiac output. The resulting increase in myocardial oxygen consumption is not compensated by coronary blood flow enhancement so that isoproterenol infusion may lead to myocardial ischemia, especially if there is preexisting coronary artery disease. Because of its proischemic and hypotensive effects, isoproterenol is no longer used as an inotropic agent in clinical practice in the absence of bradycardia.

Phosphodiesterase Inhibitors

Despite the major role of catecholamines in the management of critically ill patients with inadequate cardiac output, problems such as tachycardia, arrhythmias, increased myocardial oxygen consumption, excessive vasoconstriction, or loss of effectiveness with prolonged exposure to β -agonists may occur. Thus, other inotropic drugs as phosphodiesterase inhibitors (milrinone and enoximone) have been proposed for the management of myocardial dysfunction. These synthetic drugs inhibit the peak III isoform of phosphodiesterase, which catalyzes cAMP (see Fig. 90-1). By increasing intracellular cAMP concentration, they induce a potent vasodilation of the arterial and venous system through the relaxation of vascular smooth muscle. The left ventricular preload is reduced to a greater extent than with dobutamine. At the cardiac level, phosphodiesterase inhibitors induce an inotropic effect similar to that induced by dobutamine. The heart rate is increased only at high rates of administration. The resulting effect is an increase in cardiac output. Because the enhancement of cAMP intracellular concentration also promotes the reuptake of Ca^{2+} by the sarcoplasmic reticulum, phosphodiesterase inhibitors facilitate ventricular relaxation. Finally, since β -agonists exert their action by increasing the production of cAMP, phosphodiesterase inhibition could enhance their adrenergic effects. This is the pharmacologic basis for the synergic association of β -agonists and phosphodiesterase inhibitors.

Ca^{2+} Sensitizers

Ca^{2+} sensitizers increase the sensitivity of troponin C for Ca^{2+} and, hence, the force and the duration of cardiomyocyte contraction (see Fig. 90-1). Levosimendan is the leading drug of this therapeutic class. The advantage of levosimendan over classical inotropes would be to increase the force of contraction without enhancing the influx of Ca^{2+} into the cytosol and thus without increasing the risk of arrhythmias

related to this ionic alteration. Some degree of phosphodiesterase III inhibitory activity probably also contributes to the inotropic effect of these drugs. It also induces vasodilation by opening ATP-dependent K^+ channels.⁴³

Cardiac Myosin Activators

Cardiac myosin activators belong to a new class of inotropes. They increase the activity of ATPase of the myofibrils, increasing the contractile force of the cardiomyocytes without increasing the concentration of ATP molecules required for contraction, i.e., without increasing the myocardial oxygen consumption.⁴⁴ Additionally, these substances increase the cardiac contractile force without the potentially deleterious increase in intracytoplasmic Ca^{2+} concentration. Cardiac myosine activators have been tested in animal studies in which their inotropic properties have been well demonstrated.⁴⁵ In humans, two recent studies have demonstrated that cardiac myosin activators are a valuable new class of therapeutic agents in systolic heart failure.^{46,47} Cardiac myosin activators are well tolerated,^{46,47} including during exercise in patients with ischemic cardiomyopathy.⁴⁸ These agents improve cardiac systolic function in a dose- and concentration-related manner,^{46,47} without significant changes in diastolic function.⁴⁷ Studies in patients hospitalized for acute heart failure are ongoing (available at: www.clinicaltrials.gov, identifier: NCT01300013).

Istaroxime

Istaroxime is a new drug that inhibits Na^+/K^+ -ATPase, increasing the activity of the sarcoendoplasmic reticulum Ca^{2+} ATPase pump by relieving phospholamban inhibition.⁴⁹ It induces some inotropic and lusitropic effects.⁵⁰ In animals, istaroxime was demonstrated to decrease the end-diastolic volume of the left ventricle and increase the left ventricular ejection fraction. In patients with decompensated heart failure without hypotension, istaroxime decreased the pulmonary artery occlusion pressure and improved the diastolic function of the left ventricle.⁵¹ In patients with acute heart failure, istaroxime decreased pulmonary artery occlusion pressure, decreased heart rate in a dose-dependent manner, and increased systolic blood pressure without any effects on neurohormones or troponin levels.⁵² This drug still needs further clinical evaluation.

Nitric Oxide Donors

Nitric oxide donors improve cardiac function by direct positive cAMP-independent lusitropic and inotropic effects.⁵³ These drugs enhance sarcoendoplasmic reticulum Ca^{2+} uptake via modifications of phospholamban, sarcoendoplasmic reticulum Ca^{2+} ATPase pump, and ryanodine receptor. Moreover, nitric oxide donors improve myofilament Ca^{2+} sensitivity.⁵⁴ A human study has shown that nitric oxide donors increase cardiac output and decrease both right and left filling pressures in patients with systolic heart failure without any adverse effects.⁵⁴ This pharmacologic class also still needs further clinical evaluation.

Decrease in Beta-Adrenergic Response

It is well recognized that the response to β -adrenergic stimulation is decreased in chronic cardiac failure. This may be a response to the increased activity of the sympathetic nervous system, which may itself be a response to the reduced cardiac output. Therefore, this negative retrocontrol of the β -adrenergic response could act as a protection against excessive adrenergic stimulation. The cellular mechanisms involved are a downregulation of β_1 -adrenergic receptors and a stimulation of the G_i protein of the adenylyl cyclase system. The decrease in β_1 -adrenergic receptors could result from a decrease in β -adrenergic receptor mRNA and to an increased internalization and degradation of these receptors. These latter mechanisms are mainly related to the phosphorylation of β_1 -adrenergic receptors by the β -adrenoreceptor kinase, which is activated. The high level of nitric oxide (NO) production during heart failure contributes to the attenuation of the β -adrenergic response. The effects of exogenous

catecholamines during exacerbations of chronic heart failure can thus be reduced.

Similarly, there is evidence for a decreased responsiveness of the myocardium to beta-adrenergic stimulation during septic shock.⁵⁵ This phenomenon may occur more likely in the later phase (>24 hours) than in the early phase of the septic process.⁵⁶ This may be explained by the inhibition of adenylyl cyclase activation due to an overexpression of the Gi protein⁵⁷ at the gene level.⁵⁸

HEMODYNAMIC EFFECTS OF INOTROPIC AGENTS IN CRITICALLY ILL PATIENTS

Effects on Cardiac Output

Dobutamine

Dobutamine is the beta-adrenergic agent most widely used in critically ill patients when an increase in cardiac output through an increase in myocardial contractility is desired.

In patients with acute heart failure, dobutamine increases cardiac output and heart rate and decreases pulmonary artery occlusion pressure through a dose-response manner (from 0 to 15 $\mu\text{g/kg/min}$).⁵⁹ In patients with cardiogenic shock, dobutamine is also able to increase cardiac output while decreasing pulmonary artery occlusion pressure.⁶⁰

In patients with septic shock and depressed myocardial function, dobutamine is expected to increase stroke volume and heart rate owing to its beta1-adrenergic properties and exert a vasodilatory effect owing to its beta2-adrenergic properties. Accordingly, an increase in cardiac output and a decrease in systemic vascular resistance (SVR) with dobutamine were reported in septic patients.^{61,62} This emphasizes the need to give a potent vasopressor agent to patients with septic shock when dobutamine is administered to support cardiac function in the presence of depressed myocardial contractility. One potential advantage of dobutamine is a decrease in cardiac filling pressures that could allow an additional volume infusion to improve further cardiac output when necessary. A change from dopamine to dobutamine was shown to result in lower right and left ventricular filling pressures and an increase in right ventricular ejection fraction for the same pulmonary artery pressure and right ventricular end-diastolic volume, suggesting that dobutamine exerts a more favorable effect on cardiac contractility than dopamine.⁶³ This has justified the recommendation to administer dobutamine rather than dopamine when the use of inotropic drugs is judged necessary in patients with severe sepsis or septic shock.^{35,36} However, because of the alteration of the beta1-adrenergic pathway in the septic heart, the effect on stroke volume and cardiac output of a beta1 agonist agent such as dobutamine may be attenuated in patients with sepsis compared with those without sepsis. In this regard, infusion of dobutamine at 5 $\mu\text{g/kg/min}$, a dose able to increase cardiac output substantially in patients with acute heart failure,⁵⁹ has been reported to exert variable effects in the context of sepsis. For example, dobutamine at 5 $\mu\text{g/kg/min}$ was reported to induce a substantial increase in cardiac output in some studies in patients with severe sepsis^{61,64} but to have no significant effect on cardiac output in some studies investigating patients with septic shock.⁶⁵⁻⁶⁹ It is likely that these differences in response to dobutamine were related to various individual factors including differences in the vasopressor coadministered and in the degree of myocardial depression and/or beta-receptor downregulation. In this regard, Silverman et al. showed that incremental doses of dobutamine (0, 5, 10 $\mu\text{g/kg/min}$) produced a dose-related increase in cardiac output in patients with sepsis without shock but no increase in cardiac output in patients with septic shock, even for the highest dose.⁵⁵ Interestingly, they also found that the post-beta-adrenergic receptor signal transmission was impaired only in patients of the septic shock group and that impairment of beta-adrenergic receptor responsiveness found in both groups was significantly more marked in the septic shock group.⁵⁵ These findings, which allow divergent results of numerous studies to be reconciled,^{61,64-72} emphasize the unpredictability of the

effects of beta-agonist agents in patients with sepsis. It must be stressed that the absence of positive cardiac response to dobutamine seems to be a marker of poor outcome in septic shock patients.^{33,34,69} Because dobutamine also has potentially harmful effects (e.g., myocardial ischemia, cardiac arrhythmias), monitoring its effects on cardiac output to check its efficacy is mandatory, especially in patients who are not responding to initial therapy.³⁶

Dopamine

In patients with acute heart failure, dopamine increased stroke volume and cardiac output at 4 $\mu\text{g/kg/min}$ but not at higher doses, presumably because of an increase in left ventricular afterload. It was also reported that pulmonary artery occlusion pressure increased with dopamine while it decreased with dobutamine.⁷³ Similar results were observed in patients with cardiogenic shock receiving a dose of 15 $\mu\text{g/kg/min}$ of either agent.⁶⁰

In patients with septic shock, it was reported that the restoration of an adequate MAP with dopamine was mainly produced by the increase in cardiac output, whereas minimal effects on SVR were observed despite relatively high doses of this agent.⁷⁴ Dopamine was even demonstrated to increase cardiac output markedly while SVR fell in septic patients without shock.⁷⁵ Conversely, in another study in patients with severe septic shock, cardiac output did not increase significantly with dopamine at doses of up to 25 $\mu\text{g/kg/min}$ while SVR either did not change or significantly increased.⁷⁶ This emphasizes the great heterogeneity of the response to dopamine among patients with sepsis. This also emphasizes the difficulty to predict clinical hemodynamic effects from pharmacologic properties owing to interindividual differences in terms of the severity of the insult, underlying diseases, comorbidities, integrity of the neuro-vegetative status, drugs concomitantly prescribed, and other factors.

Epinephrine and Norepinephrine

Although these agents have beta1-adrenergic properties and are thus able to increase myocardial contractility, they are used as vasoconstrictive agents in case of severe hypotension since they also have potent alpha-adrenergic properties. Nevertheless, significant increases in cardiac output with these drugs have been reported in patients with sepsis.^{74,77,78} In this regard, norepinephrine was shown to increase cardiac output to the same extent as dopamine for the same increase in MAP.⁷⁴ However, the effects of norepinephrine on cardiac output depends on its effect on cardiac preload^{79,80} through an increase in mean systemic filling pressure.⁴¹ By contrast, epinephrine appeared as a potent inotropic agent in most studies in patients with sepsis.^{67,81-83}

Dopexamine

The pharmacologic properties of dopexamine should result in a combination of inotropic, afterload-reducing, and renal vasodilating effects, which could be useful for the management of the acute exacerbation of congestive heart failure. In this regard, dopexamine was reported to substantially increase cardiac output in patients with heart failure without altering blood pressure: at doses of up to 4 $\mu\text{g/kg/min}$, the majority of the effects resulted from an increase in stroke volume. At higher doses, the increase in heart rate made a greater contribution.⁸⁴ In cases of human sepsis, dopexamine produced a dose-dependent increase in stroke volume and heart rate but a dose-dependent decrease in SVR.⁸⁵ This underlines the marked vasodilating effect of this drug, which should not be administered in severe sepsis in the absence of a potent vasopressor. Under these conditions, dopexamine, at doses ranging from 1 to 4 $\mu\text{g/kg/min}$, could still enhance cardiac output without altering blood pressure.⁸⁶

Phosphodiesterase Inhibitors

In patients with heart failure, phosphodiesterase inhibitors significantly increased cardiac output and stroke volume, while blood pressure slightly decreased due to a decrease in SVR, confirming the combined inotropic and vasodilating effects of these agents.⁸⁷ Because of the ability of beta-agonist agents to increase cAMP levels, thereby

providing an increased substrate for phosphodiesterase inhibitors, the combination of these two types of drugs would be attractive. Synergic effects on the cardiac output of dobutamine and enoximone have been observed in patients with heart failure.⁸⁸

Ca²⁺ Sensitizers

It has been well demonstrated that levosimendan induces some beneficial hemodynamic effects in patients with acute heart failure, with an enhanced cardiac output and a decreased pulmonary artery occlusion pressure.⁸⁹ In the LIDO study, levosimendan was shown to improve hemodynamic performance more effectively than dobutamine in patients with low-output heart failure.⁸⁹ Unlike dobutamine, levosimendan can keep its effects on cardiac performance in patients receiving beta-blockers.⁸⁹

Istaroxime

Only few clinical trials studied the effect of istaroxime, a new inotropic-lusitropic agent. Two studies demonstrated that in patients with systolic heart failure, istaroxime increased cardiac index^{52,90} and decreased pulmonary artery occlusion pressure and heart rate.⁵²

Effects on Arterial Oxygen Content

The aim of inotropic therapy in critically ill patients with reduced cardiac contractility is not only to increase cardiac output but also to ultimately improve oxygen delivery to the tissues. Thus, attention should be paid to the effects of these drugs on arterial oxygen content. Inotropes may affect arterial oxygen tension through several mechanisms. First, the reduction in lung filtration pressure resulting from an improvement in cardiac function may decrease intrapulmonary shunt fraction and thus improve arterial oxygenation. Second, the increase in cardiac output may result in an increased venous admixture.⁹¹ On the other hand, the increased mixed venous blood oxygen tension resulting from increased cardiac output may improve arterial oxygenation in the presence of ventilation/perfusion mismatching and may thus compensate for the increased venous admixture. Accordingly, when looking at published data, it appears that even if the venous admixture increased with the administration of an inotropic agent, no significant change in arterial oxygen tension was observed.^{92,93} Therefore, when an inotropic agent increases cardiac output in critically ill patients, it generally increases oxygen delivery to the same extent.^{61,74,94,95}

Effects on Tissue Oxygen Utilization

Even though an inotropic agent results in a large increase in oxygen delivery, its effectiveness in reducing oxygen deficit depends on its capacity to provide oxygen in the most hypoxic tissues. This concern is particularly crucial since, first, the redistribution of blood flow is a characteristic pattern of shock states and, second, inotropic drugs may also have vasoactive properties that interact with blood flow distribution.

Cardiogenic Shock

In this setting, the redistribution of blood flow is recognized as a potent compensatory mechanism, which, in response to reduced global oxygen delivery, attempts to redirect blood flow from nonvital organs with a low oxygen extraction ratio toward vital organs with a high oxygen extraction ratio such as the heart or the brain. It must be kept in mind that the administration of drugs with vasoactive properties may interfere with the vasoregulation of regional blood flow. The extent to which this interference is beneficial in increasing oxygen supply and oxygen consumption in hypoxic areas remains speculative. This emphasizes the need to monitor, as far as possible, the perfusion and/or function of critical organs.

Septic Shock

The maldistribution of flow at the macrocirculatory level and the microcirculatory level mainly contributes to defective tissue utilization

and eventually to tissue oxygen debt in sepsis, even when systemic oxygen delivery is greater than normal. Besides sepsis-induced microthrombosis, sepsis-induced alteration in vascular reactivity is a major cause of the altered distribution of blood flow between and within organs. In addition, severe sepsis can modify the impact of endogenous catecholamines and adrenergic drugs on regional blood flows, given that a depressed vascular responsiveness to vasoactive agent is likely to occur in this setting. This hypothesis may account for the absence of the reduction of renal blood flow observed during norepinephrine administration in bacteriemic animals in comparison with controls.⁹⁶

In case of human sepsis, numerous studies examined the effects of adrenergic agents on splanchnic perfusion. Their findings have sometimes varied either because of differences in the methods used for assessing this regional circulation (e.g., gastric tonometry, laser-Doppler flowmetry, indocyanin green dilution) or because of the heterogeneity of the studied populations (e.g., differences in the severity of the septic insult, underlying diseases, or therapy coadministered). However, from the findings of majority of these studies, some reasonable conclusions can be drawn. First, dobutamine is likely to exert a beneficial effect on gut mucosal perfusion,^{62,65,67,71,97} probably via a beta2-adrenergic effect.⁹⁸ Dobutamine may also improve hepatic microcirculation via a beta1-adrenergic effect.⁹⁹ Second, dopamine may have deleterious effects on gut mucosal perfusion,⁷⁴ despite its potential vasodilating action through mesenteric dopaminergic receptors. Third, epinephrine is probably the adrenergic agent with the least desirable effects on the splanchnic vasculature as most studies showed a lower splanchnic blood flow with epinephrine than norepinephrine alone¹⁰⁰ or in combination with dobutamine,^{65,67,101} even for similar global hemodynamic effects. Fourth, dopexamine can exert a favorable effect on splanchnic perfusion¹⁰² comparable to that of dobutamine⁶⁶ and that is likely to be related to a beta2-adrenergic effect.

Regarding the effects of inotropic agents on renal circulation in patients with sepsis, two major points must be kept in mind. First, an alpha-adrenergic agent such as norepinephrine is able to increase renal blood flow and urine output,^{76,103-105} despite its potential vasoconstricting effect on the afferent glomerular arteries. This is probably due to the beneficial effect of increasing MAP when the renal blood flow is dependent of its perfusion pressure as it occurs in the presence of profound systemic hypotension. Otherwise, the sepsis-induced depressed responsiveness of afferent glomerular arteries to the action of norepinephrine cannot be excluded. Accordingly, there is more evidence that norepinephrine increases, rather than decreases, renal blood flow and urine output when given to patients with sepsis to increase the MAP toward normal values.^{76,103,104,106} Moreover, it has been demonstrated in patients with septic shock that elevating the MAP to up to 85 mm Hg with incremental doses of norepinephrine was not associated with a decrease in urine output.^{105,107,108} Second, although dopamine at low doses (<5 µg/kg/min) is pharmacologically able to vasodilate renal arteries through its action on dopaminergic receptors, the systematic administration of low doses of dopamine in critically ill patients, including patients with sepsis, does not result in improved outcome¹⁰⁹ and must no longer be recommended. Finally, no study focused on the renal effects of levosimendan in patients with septic shock. Nevertheless, a recent study showed that in postoperative cardiac patients, levosimendan infusion increased both renal blood flow and glomerular filtration, likely via its vasodilatory effects.¹¹⁰

Catecholamines can also exert proper effects on the microcirculation. First, the administration of 5 µg/kg/min of dobutamine was shown to improve sublingual microvessel perfusion measured with orthogonal polarizing spectral imaging in patients with septic shock.¹¹¹ Interestingly, these changes were independent of changes in systemic hemodynamic variables.¹¹¹ The improvement of sublingual microcirculation seems to occur only in patients with severe alterations at baseline.¹¹² Nevertheless, the effect of dobutamine on microcirculation is still debated. The administration of 5 µg/kg/min in patients with sepsis having hyperlactatemia and a cardiac index of greater than or equal to 2.5 L/min/m² failed to improve sublingual perfused vessel density or microvascular flow index, in spite of a significant increase

in systemic hemodynamics.⁹⁴ Compared to the administration of 5 µg/kg/min of dobutamine, an infusion of low doses of levosimendan improved sublingual microcirculatory blood flow patients with septic shock, probably via its vasodilatory effects.¹¹³ Two studies showed no significant effect of increasing MAP with norepinephrine on sublingual microvessels in patients with septic shock who had already been resuscitated.^{77,78} However, another study, conducted in patients with septic shock requiring norepinephrine for arterial hypotension resistant to fluid administration demonstrated that increasing the MAP from 65 to 85 mm Hg by titrating norepinephrine doses allowed the improvement of sublingual microvessel circulation.¹¹⁴ Thus, at least nonworsening or even improvement of microcirculation can result from norepinephrine infusion in patients with septic shock even when a MAP of up to 85 mm Hg is targeted. It is noteworthy that in patients with septic shock patients having a history of chronic hypertension, improved sublingual microcirculation was reported when the usual patient's level (averaged value 93 mm Hg) was targeted compared to 65 mm Hg.¹¹⁵ This result is in agreement with the results of a multicenter randomized clinical trial showing that this specific population of patients may benefit from a higher MAP target, at least in terms of renal function, than the population of patients with no chronic hypertension.¹¹⁶ Finally, inotropic drugs may also exert nonhemodynamic effects that could affect cellular metabolism and/or organ function.^{23,117} For example, the administration of epinephrine in patients with septic shock was demonstrated to increase blood lactate level independently of tissue hypoxia, by the stimulation of skeletal muscle cell Na⁺/K⁺-ATPase, which accelerates aerobic glycolysis and thus the production of pyruvate and hence of lactate into the cell.¹¹⁸ This metabolic effect is assumed to be related to the activation of the beta2-adrenergic receptors located at the surface of the skeletal muscle cells.¹¹⁹ In addition, catecholamines may modulate cytokine response to sepsis, trauma, or major surgery through beta-adrenergic receptor activation.²³ It remains to be evaluated whether this effect (inhibition of proinflammatory cytokines and enhancement of proinflammatory cytokine production) plays a beneficial role in the reversal of tissue hypoxia and organ dysfunction.

MAIN INDICATIONS OF INOTROPIC THERAPY IN PATIENTS WITH CIRCULATORY FAILURE

Acute Heart Failure and Cardiogenic Shock

For the American College of Cardiology Federation/American Heart Association, inotropic agents should be considered in patients with heart failure, in those who are refractory to other therapies, and in those who are suffering consequences from end-organ hypoperfusion.¹²⁰ In practice, inotropes should be restricted to patients with systolic dysfunction who have a low cardiac index and evidence of systemic hypoperfusion and/or congestion.¹²⁰ In the European Society of Cardiology guidelines, inotropes should be considered in patients with acute heart failure and in patients having hypotension (systolic blood pressure <85 mm Hg) and/or hypoperfusion to increase cardiac output, increase blood pressure, and improve peripheral perfusion.¹²¹ Overall, these indications clearly limit the use of inotropic agents to patients with acute heart failure and low systolic blood pressure, most likely to have increased mortality rates with a strong inverse correlation between systolic blood pressure and survival.¹²²

For the European Society of Cardiology, dobutamine is currently the first-line inotropic agent in the presence of acute heart failure with low systolic arterial blood pressure.¹²¹ For the American Heart Association, dobutamine and dopamine are both cited as inotropic agents.¹²⁰ Accordingly, the SHOCK trial registry (1190 patients) reported that dopamine and dobutamine were used in 89% and 70%, respectively, of patients with cardiogenic shock due to massive acute myocardial infarction.¹²³ However, the use of dopamine is still a matter of debate. In a study comparing dopamine and norepinephrine as the first-line

vasopressor agent in the treatment of shock, the use of dopamine was associated with a greater number of cardiac arrhythmias.¹²⁴ In addition, in a predefined subgroup analysis, the authors reported that the use of dopamine was associated with an increased risk of death in the subgroup of 280 patients with cardiogenic shock.¹²⁴

Finally, a recent multicenter placebo-controlled clinical trial demonstrated that the use of low-dose dopamine in patients with acute heart failure and renal dysfunction had no significant effect on the 72-hours' cumulative urine volume and did not improve renal function, assessed by the change in cystatin C levels.¹²⁵

Epinephrine was compared to the combination of norepinephrine and dobutamine in patients with dopamine-resistant cardiogenic shock—for example, with a cardiac index of less than 2.2 L/min/m² and a MAP of less than 60 mm Hg.¹²⁶ Epinephrine or norepinephrine-dobutamine were titrated to obtain a MAP of greater than 65 mm Hg.¹²⁶ Epinephrine infusion was as effective as the combination of norepinephrine and dobutamine to improve cardiac index and oxygen-derived parameters. Nevertheless, epinephrine infusion induced arrhythmia, increased blood lactate level, and impaired splanchnic circulation.¹²⁶

It must be stressed that the intravenous administration of catecholamines such as dobutamine is associated with an increased risk of death in patients with acute heart failure.¹²⁷⁻¹²⁹ This emphasizes their restrictive use to patients in whom pump failure results in severe hypotension and peripheral hypoperfusion.^{120,121}

Phosphodiesterase inhibitors have been proposed as an alternative to beta-adrenergic agents. However, results of trials of long-term oral phosphodiesterase inhibitor therapy in chronic heart failure and of the OPTIME-CHF study in the acute decompensation of congestive heart failure¹³⁰ have been disappointing. Thus, the use of these agents is limited to few categories of patients: (1) patients with advanced heart failure awaiting transplantation in whom intravenous milrinone could be better tolerated than dobutamine and its use may allow the continuation of beta-blocker therapy controlling arrhythmias or myocardial ischemia,¹³¹ (2) patients with acute decompensation of chronic heart failure unable to achieve stabilization with the standard treatment, and (3) patients with long-term beta-blocker use, in whom short-term intravenous milrinone may even be preferred to dobutamine. Enoximone, another phosphodiesterase inhibitor, has been tested in patients with advanced heart failure. As for milrinone, the results are disappointing. Low doses of enoximone could not improve all-cause mortality or the 6-min walk test distance.¹³² There is now clear evidence that phosphodiesterase inhibitors such as beta-agonists can exert both short-term beneficial hemodynamic effects and serious adverse effects that make them deleterious in terms of long-term outcome. It is likely that their adverse effects (e.g., arrhythmias, increased risk of myocardial ischemia) are related to the increased cAMP concentration in the cytosol of the cardiomyocyte.¹³³

The initial enthusiasm in the use of Ca²⁺ sensitizers in patients with heart failure has attenuated in recent years. In the LIDO study, compared to dobutamine, levosimendan significantly decreased mortality rate and improved the hemodynamic condition.⁸⁹ Nevertheless, these positive results have been contradicted in two large-scale studies. In the REVIVE study,¹³⁴ even though levosimendan improved the composite judgment criteria of clinical signs of heart failure at 5 days compared to placebo, the mortality rate was not significantly changed. In the SURVIVE study,¹³⁵ levosimendan was not better than dobutamine in increasing the survival rate in patients with acute heart failure requiring an inotropic support. A meta-analysis concluded that in patients with acute severe heart failure, levosimendan improved hemodynamic parameters when compared with placebo, without showing evidence of survival benefit.¹³⁶ However, a more recent meta-analysis demonstrated that levosimendan reduced mortality rate when compared to dobutamine and decreased hospital length of stay in the overall population of cardiologic patients, including but not restricted to patients with heart failure.¹³⁷ Furthermore, another topic of interest of levosimendan may be patients with heart failure receiving concomitant use of beta-blocker therapy, a situation where higher doses of dobutamine are usually required to have some efficacy. In such patients,

dobutamine was shown to be as effective as levosimendan in the first 24 hours of treatment to increase cardiac index and decrease pulmonary artery occlusion pressure.¹³⁸ However, at 48 hours, levosimendan still efficiently improved hemodynamics while dobutamine did not.¹³⁸ Moreover, when compared with placebo, levosimendan improved contractility in patients with acute heart failure following myocardial infarction,¹³⁹ and levosimendan provided rapid and durable symptomatic relief.¹⁴⁰ Nevertheless, levosimendan induced hypotension^{139,140} or cardiac arrhythmias.¹⁴⁰ Finally, a recent systematic review found no significant beneficial effects of levosimendan for low cardiac output syndromes in the general population of critically ill patients.¹⁴¹ Currently, all these disappointing results have impeded the commercialization of levosimendan in many countries.

NO synthase inhibitors have been proposed to be used in patients with cardiogenic shock, in whom NO production is increased and may exert deleterious effects on cardiac function and vascular tone.¹⁴² Tilarginine is a nonselective NO synthase inhibitor developed for treating acute heart failure. However, in the TRIUMPH study, tilarginine was unable to improve the survival rate in patients with cardiogenic shock at 3 months in comparison with placebo.¹⁴³ These negative results have interrupted the clinical development of this new drug.

Septic Shock

Treating or not treating septic-induced myocardial depression has been a matter of debate. First, it has been thought that left ventricular dilation and low ventricular ejection fraction denote adaptive mechanisms and then, if so, treating it is questionable. In this regard, left ventricular ejection fraction was reported to be lower and left ventricular end-diastolic volume to be higher in survivors,^{144,145} although a meta-analysis showed no difference between survivors for the two parameters. Second, owing to the potential, but not constant, hyporesponsiveness of the beta receptors, the efficacy of beta-agonists is not guaranteed. Third, side effects may occur with these drugs (tachycardia, arrhythmias, and hypotension). It must be stressed that there is an association of inotrope use during septic shock with mortality.¹⁴⁶ For all these reasons, inotropes and among them, dobutamine, should be not systematically administered even when a septic myocardial depression is suspected. It should be reserved for situations where cardiac dysfunction is accompanied by a low or inadequate cardiac output and signs of tissue hypoperfusion, in spite of preload optimization.³⁶ Bidimensional echocardiography¹⁴⁷ is the best tool to diagnose a severe decrease in cardiac contractility. However, bedside echocardiography is not available in all general ICUs; hence, the Surviving Sepsis Campaign recommends the use of dobutamine in septic shock in cases of (a) a myocardial dysfunction as suggested by elevated cardiac filling pressures and low CO or (b) ongoing signs of hypoperfusion, despite achieving adequate intravascular volume and adequate MAP.³⁵ Since dobutamine can exert vasodilatory effects, its use requires the concomitant use of a vasopressor such as norepinephrine. In septic shock, it is clearly recommended to use norepinephrine as the first-choice agent rather than dopamine since the latter is associated with increased mortality.¹⁴⁸ Epinephrine is a potent inotrope with vasopressive properties that could be used as an alternative of the combination of dobuta-

mine and norepinephrine. A randomized study in patients with septic shock and a presumed cardiac dysfunction found no significant difference in patient outcome between epinephrine alone and a combination of norepinephrine and dobutamine.¹⁴⁹ However, this study has been criticized for a lack of statistical power. In the condition of depressed vascular tone and reduced myocardial function, despite similar effects on systemic blood flow and pressure, epinephrine was shown to be inferior to the combination of dobutamine and norepinephrine in terms of splanchnic perfusion^{65,67,101} or to norepinephrine alone in terms of myocardial oxygen consumption.¹⁵⁰ Recently, a meta-analysis showed that the use of norepinephrine in patients with sepsis reduced mortality rate whereas the use of epinephrine did not.¹⁵¹ For all these reasons, epinephrine is not recommended as the first-choice drug when the treatment of impaired cardiac contractility is considered.⁴³ The use of levosimendan has been proposed as an alternative to dobutamine in case of severe septic myocardial depression that no longer responds to dobutamine administration.¹⁵² The rationale for using levosimendan is that the sensitivity of Ca^{2+} to myofilament is reduced during sepsis probably because of an abnormal phosphorylation of the troponin complex at the site where the Ca^{2+} ion binds to troponin C.¹⁵³ Because levosimendan can improve not only left ventricular function but also right ventricular performance through pulmonary vasodilation,^{154,155} it might be useful in cases of septic myocardial depression with associated lung injury. A recent meta-analysis including seven clinical studies in patients with severe sepsis and septic shock (246 patients) showed that levosimendan was associated with a significant reduction in mortality rate compared with standard inotropic therapy.¹⁵⁶ A multicenter randomized double-blind, parallel-group, placebo-controlled trial is ongoing to assess the efficacy of levosimendan to reduce organ failure, including cardiac dysfunction, in patients with septic shock.¹⁵⁷

It is important to note that the concept of using beta-blockers in septic conditions to prevent systemic adrenergic activation has recently emerged. In an experimental model, esmolol infusion had no significant effect on cardiac index or systemic arterial pressure and may prevent septic cardiac dysfunction by a preload effect induced by the decrease in heart rate.¹⁵⁸ In patients with septic shock, esmolol infusion was associated with a preserved stroke volume and microcirculation and a decrease in norepinephrine requirement.¹⁵⁹ In this regard, a randomized clinical trial was conducted in patients with septic shock and heart rate of greater than 90 beats/min. Esmolol infusion decreased heart rate, increased stroke volume and left ventricular stroke work index, and decreased arterial blood lactate level and fluid requirements. Although mortality rate was not the primary endpoint, it should be noted that esmolol infusion was associated with a significant decrease in 28-day mortality.¹⁶⁰ Nevertheless, patients with severe cardiac dysfunction (i.e., cardiac index ≤ 2.2 L/min/m² in the presence of a pulmonary artery occlusion pressure >18 mm Hg) were excluded. As a consequence, the presence of cardiac dysfunction during sepsis cannot be considered as an indication for beta-blockers and should be still considered as a contraindication for their use.

In summary, given all the available data, it is still recommended to choose the combination of norepinephrine and dobutamine when inotropic therapy is given to reverse cardiac dysfunction in severe sepsis.³⁵

KEY POINTS

1. Inotropic therapy is considered in patients with cardiogenic shock or in those with advanced heart failure whose condition is refractory to standard therapy. In these situations, clinicians expect short-term positive effects of intravenous inotropic drugs, allowing cardiovascular stabilization.
2. Inotropic therapy might also be considered in high-risk surgical patients, even in the absence of formally documented myocardial depression, to achieve supranormal levels of oxygen delivery during the perioperative period to prevent tissue hypoxia and organ dysfunction. Such a therapeutic attitude, which is still debated in the perioperative context, is not recommended routinely for critically ill patients with established circulatory shock.
3. Most inotropic agents enhance myocardial contractility by increasing the Ca^{2+} concentration in the cytosol of cardiomyocytes

Continued

KEY POINTS—cont'd

- after producing an increase in cytosolic cyclic adenosine monophosphate (cAMP) concentration. Synthetic and natural catecholamines enhance cAMP formation after fixing beta1-adrenergic receptors at the cellular surface while phosphodiesterase inhibitors decrease cyclic AMP degradation.
4. Beta1-adrenergic agents, such as dobutamine, dopamine, and epinephrine, are the most potent inotropic agents.
 5. Because of the downregulation of beta1-adrenergic receptors, the myocardial effects of exogenous catecholamines can be attenuated after a few days of administration.
 6. Sepsis-induced decreased responsiveness of the myocardium to beta-adrenergic stimulation may also result in the attenuation of

cardiac effects of exogenous catecholamine administration in patients suffering from septic shock.

7. The drugs given to increase cardiac contractility may also exert vasoactive effects that may interfere with the regulation of regional blood flow. The extent to which this interference is beneficial in increasing oxygen supply in hypoxic areas remains speculative. This emphasizes the need to monitor, as far as possible, the perfusion and/or function of critical organs when such agents are given to patients in circulatory shock.

ANNOTATED REFERENCES

De Backer D, Aldecoa C, Njimi H, Vincent JL. Dopamine versus norepinephrine in the treatment of septic shock: a meta-analysis. *Crit Care Med* 2012;40:725-30.

The objective of this meta-analysis was to evaluate the effects of norepinephrine and dopamine on outcome and adverse events in patients with septic shock. Six randomized studies (1408 patients) were included. Dopamine administration was associated with greater mortality and a higher incidence of cardiac arrhythmic events compared to norepinephrine administration. This paper is important since it greatly contributed to change the guidelines of the Surviving Sepsis Campaign, which now recommends to use of norepinephrine as a first-choice vasopressor and to restrict the use of dopamine to highly selected patients (e.g., patients with low risk of tachyarrhythmias and absolute or relative bradycardia).

This randomized study showed that attempting to achieve supranormal values of oxygen delivery in patients with an established critical illness may worsen rather than improve outcome.

Mebazaa A, Nieminen MS, Packer M, et al. Levosimendan vs dobutamine for patients with acute decompensated heart failure: the SURVIVE Randomized Trial. *JAMA* 2007;297:1883-91.

In 1327 patients with acute decompensated heart failure requiring inotropic support, levosimendan was compared to dobutamine in a randomized double-blind design. Despite an initial reduction in plasma B-type natriuretic peptide level in patients receiving levosimendan, levosimendan did not significantly reduce all-cause mortality at 180 days or affect any secondary clinical outcomes. These disappointing results impeded commercialization of levosimendan in many countries over the world.

Morelli A, De Castro S, Teboul JL, et al. Effects of levosimendan on systemic and regional hemodynamics in septic myocardial depression. *Intensive Care Med* 2005;31:638-44.

In 28 septic patients with persisting cardiac dysfunction after 48 h of dobutamine administration, compared to dobutamine continuation, levosimendan improved systemic hemodynamics, improved gastric mucosal perfusion and renal function, and decreased lactate. This study suggests that levosimendan might be an alternative to dobutamine for treating sepsis-induced cardiac dysfunction.

Silverman HJ, Penaranda R, Orens JB, et al. Impaired beta-adrenergic receptor stimulation of cyclic adenosine monophosphate in human septic shock: association with myocardial hyporesponsiveness to catecholamines. *Crit Care Med* 1993;21:31-9.

This clinical study demonstrated that patients with septic shock exhibit a decreased hemodynamic response to dobutamine when compared to septic patients without shock. Moreover, the stimulation of circulating lymphocytes of the studied population showed that in patients with septic shock, the degree of impairment of beta-adrenergic receptor responsiveness as well as that of post-beta-adrenergic receptor signal transmission was greater than in septic patients without shock. This study provides strong evidence of a septic shock-related myocardial hyporesponsiveness to catecholamines that may contribute to the reduced myocardial performance observed in this critical illness.

Heart disease remains the leading cause of death in both men and women among African Americans, Hispanics, and Caucasians in the United States, accounting for 1 in 7 deaths annually. Coronary artery disease was responsible for more than 375,000 deaths in 2011 as well as 650,000 admissions for a first-time acute myocardial infarction (AMI) and 300,000 recurrent infarctions.¹ Primary and secondary prevention strategies have been attributed to an overall decrease in the incidence of AMI in the United States since 1999.² Despite these encouraging data, the high incidence of obesity and heart disease among an ever-growing elderly population still accounts for a staggering number of patients who continue to require treatment for cardiogenic shock (CS) and heart failure (HF), with HF listed in over 1 in 9 death certificates.¹ The incidence of CS in myocardial infarction (CSMI) has remained relatively constant in recent decades (~7%) and remains the leading cause of death in patients with AMI.³

The lethality of CS and limited availability of donor hearts for patients with chronic HF has been the impetus for the ongoing search for an ideal form of mechanical circulatory support (MCS) over the past 60 years. The complexity and heterogeneity of this patient population have led to the development of a vast array of devices, none of which has proven optimal for support in all patients across the spectrum. The biological barriers to MCS present a constant challenge to clinicians, and the types of MCSs available are continually evolving. Accurate statistics on the worldwide utilization of all types of MCSs for CS are not known. Nonetheless, MCS remains an important adjunct in the treatment of CS and HF, with many devices demonstrating significant improvement in survival and quality of life. The lack of large prospective, randomized controlled trials (RCTs) that demonstrate clear survival advantages for many of these devices can make it difficult to discern which, if any, MCS should be used in a given clinical situation. Accordingly, the current indications, benefits, and limitations of MCS are outlined in this chapter.

HISTORY OF MECHANICAL CIRCULATORY SUPPORT

The evolution of MCS dates to the early 1950s when Gibbon developed the prototype cardiopulmonary bypass (CPB) apparatus.⁴ In the years that followed, Lillehei, Kirklin, and others applied the heart-lung machine to facilitate open-heart surgery; their pioneering work and early observations led directly to the development of modern MCS systems.⁵⁻⁷ Their initial publications introduced the concept that left ventricular (LV) decompression and myocardial rest could afford enhanced cardiac recovery after the insult of open-heart surgery. Clinical use of extracorporeal CPB for heart surgery became widespread in the early 1960s. Simultaneously, several groups of investigators were testing means of MCS for use outside the operating room to support patients in CS. The current modes of MCS are derivations of those originally developed.

The decision on the type of MCS used is based on the acuity of the patient's presentation and the overall goals of therapy. This decision often changes as the patient's clinical picture evolves. MCS devices include the intraaortic balloon pump (IABP), continuous flow pumps with or without an oxygenator, and pulsatile pumps. Temporary MCS devices are utilized in CS as a bridge to recovery (BTR),

bridge-to-bridge ("double bridge") with a long-term implantable MCS device, bridge to transplant (BTT), or until definitive corrective surgery can be performed. Some temporary MCS devices can be inserted percutaneously, while others require surgical implantation. Long-term MCS devices are used as a BTR, a BTT, or as the definitive means of treatment for the patient's remaining lifespan—that is, destination therapy (DT). These devices have been employed for a variety of causes of CS including AMI, inability to wean from CPB (postcardiotomy failure), acute decompensation of chronic HF, acute myocarditis, peripartum cardiomyopathy, HF secondary to acute or chronic valvular heart disease, and congenital heart defects.

History of Aortic Counterpulsation

The concept of arterial counterpulsation was introduced in 1961 by Clauss and coworkers. It involved use of an external "ventricular" chamber that filled with blood from a catheter in the iliac artery and was subsequently compressed by a piston. Compression of the "ventricle" was synchronized to either the QRS complex of an electrocardiogram (ECG) or the impulse of a pacemaker so that a counterpulse of blood was delivered into the arterial system during diastole.⁸ It was demonstrated in dogs that cardiac stroke work and LV end-systolic pressures were substantially reduced with the use of a counterpulsation into the aorta. The following year, Mouloupoulos and associates adapted the model to create an IABP that could provide a similar counterpulsation without the need for blood reservoirs.⁹ The investigators used a balloon that was rapidly inflated and deflated with carbon dioxide during native diastole. The IABP was subsequently adapted and described for clinical use by Kantrowitz and colleagues in 1968.¹⁰ There is little difference in the modern IABP and that originally described, other than the availability of different-sized balloons (30- to 50-mL balloons), the use of helium instead of carbon dioxide, and subtle differences in the materials used to make the catheters.

History of Mechanical Assist Devices

The need for effective MCS devices became apparent in the 1950s during the development of CPB for open-heart surgery. The first attempt at isolated extracorporeal LV support was with a simple roller pump in 1962.¹¹ Initial attempts with prolonged postoperative CPB demonstrated that the bypass circuit was damaging to both end organ function and blood constituents after several hours of use.¹² Subsequently, femoral venous-to-femoral arterial CPB was successfully used by Spencer and colleagues in four patients with postcardiotomy cardiac failure.¹³ Simultaneous to Spencer and colleagues' work with extracorporeal systems, DeBakey designed the first intracorporeal LV assist device (LVAD), the DeBakey blood pump.¹⁴ A remodeled extracorporeal version was subsequently used for postcardiotomy failure in a 37-year-old woman after aortic and mitral valve replacements. The device was needed for 10 days, and the patient survived.¹⁵

By 1972, investigators at the Texas Heart Institute had developed a pneumatically driven LVAD designed to be implanted in the abdomen.¹⁶ This device had a blood chamber compressed by pulses of air delivered into the pump by a percutaneous driveline. Modern devices have chamber compression that is electrically powered via percutaneous drivelines. Paracorporeal, pneumatically driven devices were a parallel

development. Paramount to the evolution of these devices was the sponsorship of the Artificial Heart Program of the National Heart, Lung, and Blood Institute, which was chartered in 1964.

By the 1960s, continuous flow, as compared to pulsatile, pumps were under development.^{17,18} Over the subsequent 15 years, continuous flow centrifugal pumps were perfected and introduced into clinical use. These pumps work on the principle of a forced, constrained vortex devised from three magnetic cones.^{19,20} They have been shown to be useful in a variety of clinical settings where short-term MCS is needed and an IABP is inadequate. Several types of small, axial-flow, or rotary pumps have also been developed, including some that allow for percutaneous deployment.²¹⁻³⁴ These pumps generally contain a magnetically suspended impeller that rotates at extremely fast rates (25,000 to 35,000 rpm). The axial rotary pump technology has some potential advantages over pulsatile devices: they are quite small with few moving parts and do not require a compliance chamber. The latest generation of rotary pump technology utilizes fully magnetically levitated rotors that completely eliminate the need for seals or bearings. This technology reduces the risk of damage to blood elements and may lead to lower rates of thromboembolism.

CURRENT USE OF MECHANICAL CIRCULATORY SUPPORT DEVICES

Temporary Mechanical Circulatory Support

Percutaneous Insertion

Intraaortic Balloon Pump. The physiologic rationale for the efficacy of the IABP is that balloon deflation provides a rapid, synchronized reduction in impedance (afterload) during isovolemic LV contraction. This is followed by a rapid, synchronized increase in aortic pressure during isovolemic LV relaxation (diastolic augmentation) caused by balloon inflation. In combination, these events achieve two important goals. First, LV systolic unloading directly reduces stroke work, which in turn reduces myocardial oxygen consumption during the cardiac cycle. Second, diastolic augmentation raises arterial blood pressure and provides better coronary arterial perfusion during diastole, yielding increased oxygen delivery to the myocardium. The IABP does not directly move or redistribute blood flow; however, peak diastolic coronary flow velocity can be increased as much as 87% with IABP augmentation and peak diastolic flow velocity by as much as 117%.³⁵ Since its introduction into clinical use in 1968, the IABP has remained an important adjunct to supporting patients in CS. Myocardial recovery is promoted by the reduction of cardiac work and the simultaneous increase in myocardial oxygen supply. However, therapeutic success is dependent on the patient having a minimum degree of LV function that, in combination with IABP support, facilitates an adequate cardiac output (CO) to sustain end organ function. When this minimal CO is not met, alternative MCS must be considered.

The absolute indications for IABP placement include CS, uncontrolled angina pectoris, acute postinfarction ventricular septal defect (VSD),³⁶ postinfarction mitral regurgitation (MR) secondary to papillary muscle rupture, and postcardiotomy left-sided HF with low CO. In these settings, IABP should be considered as a primary therapy that should not be delayed until signs of systemic malperfusion are clinically evident. It is important to recognize that blood pressure alone is not an adequate indication of hemodynamic or cardiac stability. Limb perfusion, renal function, mental status, and even gastrointestinal function need to be considered in the assessment of adequate resuscitation and homeostasis. Additional measurable indices include arterial (SaO₂) and mixed venous oxygen saturation (SvO₂), acid-base status, urine output, and body temperature. A multivariate analysis of data accrued from 391 postcardiotomy patients requiring an IABP demonstrated that epinephrine requirements greater than 0.5 µg/kg/min, a left atrial pressure greater than 15 mm Hg, urine output less than 100 mL/h, and SvO₂ less than 60% correlated with mortality.³⁷

These criteria were used to help predict mortality and the need for subsequent MCS.

Other relative indications for IABP use include (1) high-risk, catheter-based interventional procedures such as left main coronary artery angioplasty, (2) after unsuccessful attempts at catheter-based intervention in patients with poorly controlled ventricular arrhythmias and concomitant poor LV function, and (3) in settings of persistent stunned, ischemic myocardium. These are circumstances in which reduction of LV systolic wall tension and oxygen consumption by the IABP might enhance myocardial recovery after intervention. The Benchmark Counterpulsation Outcomes Registry of IABP use in 22,663 patients from 250 hospitals worldwide demonstrated that CS and high-risk angioplasty were the most common indications for utilization of the device.³⁸ Table 91-1 depicts a further characterization of the Benchmark report with respect to indications for use of the IABP and subsequent interventions.³⁹

The optimal site of insertion of an IABP is a common femoral artery that can be accessed either percutaneously with the Seldinger technique or by surgical cutdown. Modern intraaortic balloon catheters are available for adults and children, according to the appropriate size and length for a given height and weight of the patient. Adult intraaortic balloons have a range in volume filled between 30 and 50 mL, with a standard balloon size holding 40 mL of helium. IABP catheters placed through the femoral artery are positioned so that the tip is just distal to the takeoff of the left subclavian artery in the proximal descending thoracic aorta. Optimally, the tip of the catheter should be positioned with transesophageal echocardiographic or fluoroscopic guidance.⁴⁰ To reduce the diameter of femoral cannulation, the sheathless IABP technique can be utilized and is our preferred method.⁴¹

Inflation of the balloon should be timed with closure of the aortic valve (at the dicrotic notch of the aortic pressure tracing) and should be inflated to nearly occlude the descending thoracic aorta. Timing can be synchronized in one of three ways: (1) using an arterial (preferably aortic) pressure tracing in synchrony with the dicrotic notch, (2) using the descent of the R wave on a rhythm tracing, or (3) timed after a ventricular pacing spike when a pacemaker is in use.⁴²⁻⁴⁶ The optimal physiologic benefit of the IABP is significantly improved by proper timing of inflation and deflation, which can be difficult when there is an accelerated heart rate, cardiac rhythm disturbances, atrioventricular dyssynchrony, or low mean arterial pressure. Timing should be adjusted to maximize diastolic augmentation; hence, deflation should be as late as possible but just before opening of the aortic valve. If this cannot be gauged by pressure tracing, it can be timed to the onset of the R wave on ECG tracing or with the use of M-mode echocardiography.⁴⁷

When femoral arterial cannulation is not desirable due to aortoiliac occlusive disease or extensive peripheral vascular disease (PVD), the subclavian artery or the ascending aorta can be utilized.⁴⁸⁻⁵² With either technique, the IABP catheter is advanced antegrade down the descending thoracic aorta so that the balloon tip sits above the level of the diaphragmatic hiatus, and the most proximal end of the balloon is distal to the takeoff of the left subclavian artery. These antegrade balloons should always be placed with either fluoroscopic or echocardiographic guidance. They should be removed with open arterial repair in all cases.

IABP catheters should not be left in place after weaning because of the risk of thrombus formation and embolization. An IABP should be weaned stepwise from a rate that is equivalent to heart rate (1:1) down to a ratio of 1:4 just before removal. Balloon catheters placed via the open surgical technique should also be removed surgically. Percutaneous removal of catheters placed in the iliac artery above the inguinal ligament (often done in obese individuals) can result in significant retroperitoneal bleeding. Consideration of operative removal is warranted.

Relative contraindications to IABP use include severe atherosclerotic disease of the descending thoracic aorta, descending aortic dissection or aneurysm, recent descending thoracic aortic surgery, and mild to moderate aortic insufficiency. Severe aortic insufficiency is

AMI, acute myocardial infarction; CABG, coronary artery bypass graft; PCI, percutaneous coronary intervention; VA, ventricular arrhythmias.

Modified from Ferguson JJ 3rd, Cohen M, Freedman RJ Jr, et al. The current practice of intra-aortic balloon counterpulsation: results from the Benchmark Registry. *J Am Coll Cardiol* 2001;38:1456–1462.

an absolute contraindication to use because diastolic augmentation cannot be accomplished and LV end-diastolic volume and pressure are actually increased rather than decreased.

The overall complication rate of IABP utilization is between 5% and 10%. Major complications occur at a rate of about 3% and include severe bleeding, major limb ischemia or amputation, infection, visceral or spinal cord ischemia, and attributable IABP mortality.^{38,53} In the Benchmark registry, rates of complications were quite low; the most common complications were access site bleeding (4.3%) and limb ischemia (2.3%). The rates of amputation, stroke, visceral or spinal cord ischemia, and IABP-related mortality were all 0.1% or less.³⁹ Intraaortic balloon entrapment is a rare complication.^{54–56} The incidence of major vascular complications according to the STS National Database (1996–1997) and the Benchmark Registry (1997–1999) was 5.4% and 1.4%, respectively.^{39,53} Ipsilateral limb ischemia should be immediately addressed after its recognition. This usually requires removal of the IABP with replacement at another location if it is still indicated. The ischemic limb may require thrombectomy with or without revascularization and fasciotomy.^{57–63}

Despite the widespread use of IABP in thousands of patients worldwide each year, no prospective RCT has ever demonstrated a survival benefit with IABP use in a patient population undergoing high-risk catheter intervention. The use of an IABP had no impact on mortality rates in a population of patients without hemodynamic instability undergoing high-risk angioplasty randomized in a prospective trial reported in 1997.⁶⁴ In contrast, the SHOCK trial showed that early revascularization in CSMI, often facilitated by IABP use (86%), yielded a lower 6-month mortality rate (50%) than that with medical therapy alone (63%).³ Additional studies have shown that in patients undergoing urgent or emergent revascularization after an AMI, those supported preoperatively with an IABP had a lower operative mortality than those in whom an IABP was not used (5.3%–8.8% vs. 11.8%–28.2%).^{53,65} These data seem to justify a strategy of aggressive IABP use to facilitate early revascularization in a postinfarction patient. The Second Angioplasty in Myocardial Infarction (PAMI-II) Trial data examined high-risk patients with AMI revascularized by percutaneous coronary intervention (PCI) only and demonstrated a modest survival advantage at 6 months with the use of periprocedural IABP

support.⁶⁴ When evaluating hospital mortality rates among patients undergoing coronary artery bypass graft (CABG) and/or valve surgery who received preoperative IABP or required intraoperative/postoperative IABP support, the mortality rate was significantly lower among patients supported preoperatively as depicted in [Table 91-2](#).^{39,53} Hence, there appeared to be a survival advantage to earlier IABP support for patients with CSMI who undergo revascularization. In the setting of an acute VSD or acute MR after an AMI, IABP support can offer a dramatic improvement in the hemodynamic response of the patient.^{66–71} [Figures 91-1](#) and [91-2](#) stratify hospital mortality rates associated with IABP use in patients with AMI by principal usage indication or by performance of PCI or CABG. It is clear that the mortality rate of patients in CSMI remains high at 39%. However, these studies suggest that IABP support, combined with revascularization, portends a better prognosis than adjunctive IABP use with medical therapy alone.³⁸ This benefit is likely greatest in those who are revascularized and present with Class 3 or 4 HF.⁷² A recent meta-analysis of 16 studies demonstrated a significant survival benefit for the use of IABP in CSMI (RR: 0.78; CI: 0.60–0.86; $P < 0.0004$).⁷³ However, no benefit was seen in patients with high-risk AMI that was not complicated by CS.

Conversely, a recent Cochrane Database meta-analysis of six RCTs reviewed the use of IABP in CSMI in 190 patients and found no significant improvement in in-hospital, 30-day, or 6-month all-cause mortality.⁷⁴ An update of the review in 2015 drew the same conclusions.⁷⁵ A meta-analysis of cohort studies of IABP use in patients in CSMI by Sjauw et al. found an 18% decrease in 30-day mortality in patients treated with thrombolysis and IABP. However, in patients treated with PCI, they noted a 6% increase in mortality associated with the additional use of an IABP.⁷⁶ In the prospective IABP-SHOCK II Trial, 600 patients in CSMI were randomized with and without placement of IABP after undergoing revascularization, primarily with PCI (>95%).⁷⁷ No difference in the primary endpoint of 30-day, all-cause mortality was seen (39.7% IABP, 41.3% control). However, a 10% crossover to the IABP arm was noted. Additionally, a meta-analysis of 12 RCTs found no improvement in 30-day mortality with the use of IABP in patients with AMI, regardless of whether or not the patients suffered from CS.⁷⁸ From this compilation of results, it may

TABLE 91-2

Hospital Mortality (Outcome Parameter) for Patients Undergoing Cardiac Surgery Who Either Received Preoperative IABP or Intra-/Postoperative IABP Support

| TYPE OF THERAPY | BENCHMARK REGISTRY 1997-1999 MORTALITY/ TOTAL OPERATIONS WITH IABP, N (%) | STS NATIONAL DATABASE 1996-1997 MORTALITY/ TOTAL OPERATIONS WITH IABP, N (%) | STS NATIONAL DATABASE 1996-1997 MORTALITY/ TOTAL OPERATIONS WITHOUT IABP, N (%) |

Based on data from the Benchmark Counterpulsation Registry 1997-1999 and the STS National Database 1996-1997 compared with hospital mortality for patients who had neither preoperative nor intraoperative/postoperative IABP support.

From Christenson JT, Cohen M, Ferguson JJ 3rd, et al. Trends in intraaortic balloon counterpulsation: complications and outcomes in cardiac surgery. *Ann Thorac Surg* 2002;74:1086-1090. Tab 4.

FIGURE 91-1 ■ In-hospital mortality of 5495 patients with acute myocardial infarction (AMI) requiring intraaortic balloon pump counterpulsation, stratified by principal usage indication. PCI, percutaneous coronary intervention. (From Stone GW, Ohman EM, Miller MF, et al. Contemporary utilization and outcomes of intra-aortic balloon counterpulsation in acute myocardial infarction: the Benchmark registry. *J Am Coll Cardiol* 2003;41:1940-1945.)

be concluded that the use of IABP in CSMI has little benefit in any treatment strategy that does not employ the use of early revascularization (primarily with PCI). Furthermore, improvement in the patient's hemodynamics often seen with the use of IABP does not suffice as a surrogate marker for survival in patients in CSMI. An IABP should be placed in the case of acute postinfarction VSD or acute MR without delay. Along with early revascularization, it should be considered in the armamentarium of MCS in patients in CSMI until further RCTs more clearly delineate those patients who are most likely to derive benefit.

Extracorporeal Membrane Oxygenation (ECMO). Since the 1970s, ECMO has been utilized in the adult population for short-term (1 to 10 days) MCS when CS is complicated by concomitant pulmonary insufficiency. It provides full cardiopulmonary support to allow reversal of the systemic malperfusion that occurs in CS until definitive surgical correction is performed. It can also serve as a BTR, a BTT, or a bridge-to-bridge to longer term MCS (i.e., VAD).⁷⁹⁻⁸¹ It may be employed for a period of 1 to 3 days in cases when the neurologic status of a patient is unclear and longer term support may not be appropriate until this status is clarified.

The ECMO circuit consists of inflow and outflow cannulas, a continuous flow centrifugal pump, a hollow-fiber oxygenator, and a heat exchanger. Historically, roller pumps and centrifugal pumps have both been utilized. Roller pumps remain in widespread use for CPB

FIGURE 91-2 ■ In-hospital mortality stratified by the performance of angiography and percutaneous or surgical coronary revascularization. (From Stone GW, Ohman EM, Miller MF, et al. Contemporary utilization and outcomes of intra-aortic balloon counterpulsation in acute myocardial infarction: the Benchmark registry. *J Am Coll Cardiol* 2003;41:1940-1945.)

during cardiac surgery; applications outside the operating room have been virtually abandoned due to higher rates of circuit disruption, particle emboli, and hemolysis.^{82,83} Bio-Medicus Biopump (Medtronic, Corp., Minneapolis, MN) and CentriMag (Levitronix LLC, Waltham, MA) are two centrifugal pumps commonly used in ECMO circuits. The Bio-Medicus Biopump generates a constrained vortex within an acrylic shell that houses concentric magnetic cones. The cones rotate as a magnetic rotary motor spins adjacent to the base of the cones^{19,20,84} and can generate very high flows with less trauma to blood cells than roller pumps.^{83,85,86} The cannulation strategy most often used in acute CS is peripherally via the femoral vessels with either the percutaneous Seldinger or surgical technique. Alternatively, central cannulation via the right atrium (RA) and aorta is used to provide temporary MCS in the case of postcardiotomy failure. When faced with postcardiotomy ventricular failure, MCS with these pumps can facilitate patient stabilization for subsequent transport to a tertiary medical center for VAD placement. A recent addition to the array of ECMO systems is CardioHelp (Maquet Cardiopulmonary AG, Hechingen, Germany). It is a miniaturized system that combines the pump and oxygenator in a single unit (Fig. 91-3). It can be easily carried in one hand, making it ideal for patients who require urgent interhospital transport.⁸⁷

Disadvantages in using the peripheral cardiopulmonary support or ECMO include the greater potential for ipsilateral limb complications, higher rates of hemolysis, the requirement for anticoagulation to prevent thrombosis of the oxygenator and circuit, and failure to adequately decompress the left ventricle.⁸⁸⁻⁹⁴ Inadequate LV decompression with peripheral cardiopulmonary support/ECMO systems may be the mechanism responsible for some treatment failures.

FIGURE 91-3 ■ (A) Front view of the Maquet CardioHelp console. The line set can be seen hanging on the wall behind the pump. The device can be carried with one hand by the handle as seen on top of the device. (B) View of the back of the CardioHelp demonstrating the oxygenator directly attached to the pump, creating a compact unit that is very amenable to transport. (With permission from Maquet BV, Rastatt, Germany.)

Regardless of the etiology of CS, a rested ventricle (i.e., decompressed) has a better chance of recovery than a distended ventricle. Lower extremity ischemia may be resolved or prevented by placing an additional perfusion cannula (8 to 14F) down the ipsilateral superficial femoral artery.⁹⁵ Alternatively, limb ischemia may be prevented with the use of an 8-mm T-graft sutured to the side of the femoral artery.⁹⁶ However, this increases the complexity of instituting ECMO and can be impractical in CS.

The use of ECMO in the adult population for reasons other than primary cardiac failure with secondary pulmonary insufficiency has limited advantages over conventional therapies.^{97,98} However, a substantial subset of patients who present with CS and are initially resuscitated with cardiopulmonary support/ECMO survive to revascularization, transplantation, or recovery, with survival rates as high as 75%.⁹⁹⁻¹⁰⁹ ECMO used as a bridge to VAD placement for profound CS ("double bridge" mechanical assistance) can yield survival rates higher than 40%.¹¹⁰ This strategy is pragmatic and offers immediate end organ support while a subsequent definitive treatment plan can be designed. In an outcome study by Combes et al., early predictors of death on ECMO support include hepatic failure, renal failure, or placement of ECMO while undergoing CPR. Of the greater than 40% who did survive to discharge, many reported continued physical and social problems, including the ability to return to work.¹¹¹ This underscores the importance of long-term follow-up and the need for continued psychosocial support of these patients.

Improvements in pump and oxygenator technology have made EMCO a relatively simple means to establish MCS, allowing reversal of end organ malperfusion that inevitably accompanies CS not promptly corrected with medical therapy alone. However, complications of bleeding, infection, stroke, and limb ischemia increase with time and limit this means of support to approximately 7 days.¹¹² As with any form of MCS, the plan for separation from support or transition to a more permanent means begins upon institution of ECMO. Once end organ malperfusion has been corrected, the feasibility of ECMO weaning is determined on a daily basis. Weaning trials are guided based on the patient's hemodynamic parameters, oxygenation, and ventilation. Pulmonary and circulatory support can be weaned independently or simultaneously. Pulmonary weaning consists of increasing support from mechanical ventilation, while the amount of

FIGURE 91-4 ■ (A) Components of the TandemHeart device: 21F left atrial drainage cannula and 15-17F femoral arterial cannula (left); continuous flow centrifugal pump (right). (B) Schematic demonstrating transeptal left atrial drainage and femoral access points. (From Windecker S. Percutaneous left ventricular assist devices for treatment of patients with cardiogenic shock. *Curr Opin Crit Care* 13:521-527. Copyright 2007, Lippincott Williams & Wilkins.)

oxygenation and ventilation provided by ECMO is dialed down. Circulatory weaning is done by gradually decreasing the amount of pump flow in a stepwise fashion, while assessing hemodynamic parameters. This is also guided by the use of transthoracic or transesophageal echocardiography to evaluate the cardiac response to ventricular loading that occurs with decreasing pump flow. Once it is determined that the patient can maintain adequate perfusion and pulmonary function, a plan is made to separate the patient from ECMO and remove the cannulas. The cannulas are most often removed in the operating room with direct vascular repair of the femoral vessels. If the patient cannot be successfully weaned from EMCO, the plan for conversion to VAD or transplant is undertaken. This period of support, weaning, and determining the long-term strategy is done with the collaboration of a multidisciplinary team of surgeons, cardiologists, and critical care providers.

TandemHeart. The TandemHeart System (Cardiac Assist, Inc., Pittsburgh, PA) is an external centrifugal pump system that allows for percutaneous LV support by pumping blood from the left atrium into the femoral artery (Fig. 91-4).¹¹³ Placement of the 21F venous inflow cannula is performed in the cardiac catheterization laboratory by accessing the femoral vein percutaneously and positioning the cannula tip in the left atrium via an atrial transeptal puncture. Outflow is established into the contralateral or ipsilateral femoral artery via a 15F or 17F cannula. The centrifugal pump is strapped to the thigh adjacent to the arterial cannula. The device contains a built-in heparin delivery system to decrease thrombin formation. An experienced team can establish MCS with TandemHeart in as little as 1 hour.¹¹⁴ However, this is still longer than required for institution of ECMO. Therefore, its use may be limited in truly emergent cases and in conditions requiring CPR.

Contraindications to placement of TandemHeart include severe PVD and isolated right ventricular (RV) failure. It also cannot be used in the presence of a VSD due to the potential for right-to-left shunting.¹¹⁵ Right-to-left shunting is a known complication that can also occur if the transeptal cannula becomes dislodged into the RA. Other complications include limb ischemia and thromboembolism.

TandemHeart has mostly been utilized as an MCS in CS.¹¹⁶⁻¹¹⁸ Support has been employed for various indications including postcardiotomy failure,¹¹⁹⁻¹²¹ until corrective valvular surgery is performed,¹²²⁻¹²⁴

until recovery of fulminant myocarditis,^{125,126} or as a bridge to LVAD or BTT.^{118,127,128} It has also been utilized successfully for MCS during high-risk PCI.¹²⁹⁻¹³² TandemHeart has been shown to be a more effective means of improving hemodynamic parameters in CS than IABP; however, no improvement in 30-day mortality has been demonstrated.^{133,134}

Impella Recover. The most recent addition to the armamentarium for acute short-term MCS is the Impella Recover axial flow pump (Abiomed, Inc., Danvers, MA) (Fig. 91-5). The device is placed retrograde across the aortic valve with the tip situated in the LV. It can be placed percutaneously or surgically via the femoral artery under fluoroscopic guidance. It may also be placed surgically via an 8-mm T-graft sewn to the subclavian artery^{135,136} or directly into the ascending aorta during cardiac surgery. There are two versions of Impella: the 2.5 and 5.0 (flow rates of 2.5 and 5.0 L/min, respectively). While the 2.5 can be placed percutaneously or surgically, the larger 5.0 requires surgical placement. Contraindications for the use of Impella include patients with severe aortic stenosis and those who have had a previous mechanical aortic valve replacement. Severe PVD may make percutaneous deployment impossible or mandate a surgical cutdown for placement.

Similar to other devices, Impella has been used for MCS for several indications including high-risk PCI,¹³⁷⁻¹³⁹ postcardiotomy failure,¹⁴⁰⁻¹⁴²

CSMI,^{117,143-146} severe allograft rejection following heart transplant,^{147,148} myocarditis,^{149,150} and as a bridge to placement of a long-term device, BTR, or BTT.¹¹⁷ RCTs comparing support with Impella 2.5 versus IABP in CSMI have demonstrated improved hemodynamic and laboratory parameters (CI, mean arterial pressure, serum lactate levels) with the use of Impella.^{133,151} However, this did not translate into improved 30-day survival. In contrast, the recent PROTECT-II randomized trial comparing these two devices in high-risk PCI demonstrated lower rates of the two composite endpoints of major adverse events (MAE) and major adverse cardiac and cerebral events (MACCE = death, stroke, myocardial infarction, and repeat revascularization).¹³⁷ At the 3-month follow-up, the rates of both composite endpoints were lower in the Impella group than in the IABP group (MAE, 37% vs. 49%, $P = 0.014$; MACCE, 22% vs. 31%, $P = 0.034$) at 3 months.

Surgical Insertion

Short-term MCS using continuous-flow pumps for CS is a relatively simple means of establishing immediate and complete MCS, requiring no additional equipment other than that needed for standard CPB support during cardiac surgery. As previously discussed, some MCS pumps can be utilized with percutaneous cannulation for ECMO support. These same pumps may be placed by surgical insertion. The most common indication for temporary MCS where surgical insertion is used is for postcardiotomy CS. This can be achieved by conversion from the CPB circuit used during the primary cardiac operation to a temporary VAD system, using the existing cannulas in the RA and aorta. Temporary VAD support may be required for several days to allow myocardial recovery. If the decision is made to leave the chest open, the cannulas can be brought out through the lower portion of the sternotomy incision and covered with a sealed temporary dressing. Alternatively, they can be brought out through separate incisions inferior to the sternotomy, allowing the sternum to be closed temporarily. The patient can then be brought back to the operating room within several days to explant the cannulas once cardiac recovery has occurred or converted to a long-term LVAD. In addition, MCS in postcardiotomy failure can be carried out by converting to peripheral cannulation. This allows for definitive closure of the chest, provided the patient can be successfully weaned from MCS and will not require a long-term VAD or transplant. Postcardiotomy MCS can be withdrawn in cases where severe multiorgan failure ensues despite therapy or conversion to long-term MCS is not appropriate (advanced age, lack of appropriate psychosocial support). However, it is best to determine candidacy for long-term MCS and discuss the goals of treatment prior to performing any high-risk surgical case.

CentriMag Ventricular Assist. The CentriMag system utilizes fully magnetically levitated technology (Fig. 91-6) to provide MCS in a fashion similar to the BioMedicus Biopump. The CentriMag system has many advantages that make it attractive for temporary MCS in the acute setting.¹⁵² These advantages include ease of implantation, direct outflow cannulation of the ventricle for improved decompression, minimal need for anticoagulation, and less damage to blood elements compared to traditional devices such as the Bio-Medicus pump. It has been used effectively for uni- or biventricular support in the setting of postcardiotomy failure as a bridge to decision, BTR, or bridge to a long-term MCS device. For patients with concomitant pulmonary insufficiency, an oxygenator may be spliced into the circuit, effectively converting it to an ECMO system.

ABIOMED BVS 5000 and AB 5000. The ABIOMED biventricular system (Abiomed, Inc., Danvers, MA) is a pulsatile, temporary MCS system that is available in two versions. The FDA-approved ABIOMED AB 5000 “ventricle” replaces the previously utilized BVS 5000, which was developed in the 1980s and was granted approval for use for postcardiotomy HF by the U.S. Food and Drug Administration in 1992.¹⁰⁷ Since that time, indications for the device have been broadened to include patients with either postcardiotomy shock or precardiotomy shock who do not adequately respond to inotropes and an IABP. The ABIOMED system is a pneumatically driven, dual-chamber blood

FIGURE 91-5 ■ (A) Schematic demonstrating retrograde placement of the Impella Recover LP 2.5 device across the aortic valve. (B) Components of the device. Blood from the ventricle enters the inlet portion of the device and is propelled by a 12F microaxial pump to the outlet portion positioned in the ascending aorta, establishing left ventricular decompression. (From Windecker S. Percutaneous left ventricular assist devices for treatment of patients with cardiogenic shock. *Curr Opin Crit Care* 13:521–527. Copyright 2007, Lippincott Williams & Wilkins.)

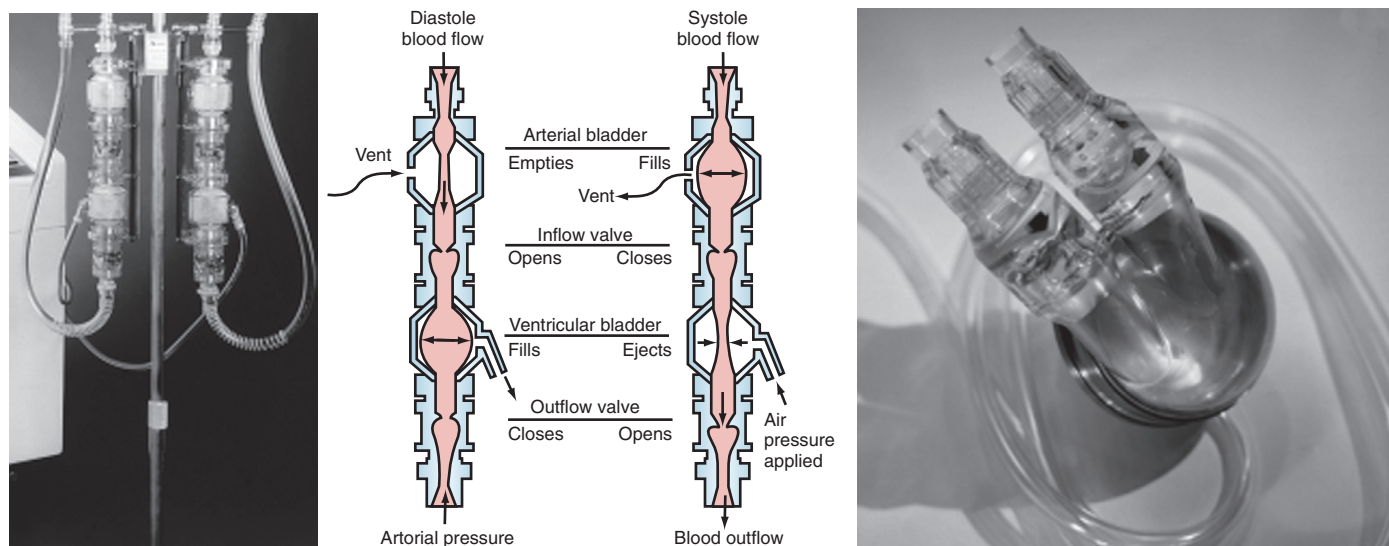

FIGURE 91-7 ■ The ABIOMED BVS 5000 and AB 5000. Left, In the BVS5000 model, the atrial chamber empties through a one-way valve into the ventricular chamber (diastole). The pneumatically driven pump compresses the ventricular chamber, and blood flows through a one-way valve into the patient (systole). The atrial chamber fills by gravity during pump systole. Right, In the AB 5000 model, a single ventricular blood chamber fills by vacuum assistance, and blood is ejected by pneumatic inflation of a polyurethane bladder housed within the pump casing. (From Couper GS, Dekkers RJ, Adams DH. The logistics and cost-effectiveness of circulatory support: advantages of the ABIOMED BVS 5000. *Ann Thorac Surg* 1999;68:646–649. Copyright 1999, The Society of Thoracic Surgeons; Moazami N, McCarthy PM. Temporary circulatory support. In: Cohn LH, Edmunds LH Jr, editors. *Cardiac surgery in the adult*. New York, McGraw-Hill; 2003.)

pump that delivers pulsatile flow. The pumps, as depicted in Figure 91-7, are extracorporeal (BVS5000) or paracorporeal (AB5000). The BVS5000 is generally useful for short-term (<7–10 days) support because of the increased risk of thromboembolic complications or device malfunction beyond this period. If longer support (2–3 months) is necessary, the ABIOMED pump can be exchanged with AB5000 or converted to a long-term VAD system such as Thoratec PVAD or HeartMate.

ABIOMED VADs have been placed for precardiotomy or postcardiotomy cardiac failure.^{153–157} Survival and hospital discharge rates have ranged from 20% to 45%, depending on the indication for the ABIOMED and the hemodynamic condition of the patient before surgery.^{154–157} The most common complications directly attributed

to this VAD include bleeding, stroke, and infection, with rates of 20% to 40%.^{154,155,157} Advancements in pump technology have contributed to the ABIOMED system's waning importance in the field of MCS.

Long-Term Ventricular Assist Devices

Pulsatile Devices

Early evidence suggested that pulsatile MCS offers improved end-organ perfusion and lymphatic flow and was thus beneficial.^{157–159} VADs that utilize direct cardiac outflow cannulation (VAD inflow) provide better ventricular decompression and rest than peripheral bypass support systems. Several MCS devices achieve these goals,

including the previously mentioned temporary, extracorporeal ABIOMED AB 5000. Long-term pulsatile devices from the Thoratec Corporation (Pleasanton, CA) include the paracorporeal Thoratec PVAD and two implantable, intracorporeal devices: Thoratec IVAD and HeartMate XVE LVAD. Last, full cardiac replacement has been achieved with pulsatile CardioWest Total Artificial Heart (SynCardia Systems, Inc., Tucson, AZ). These devices have been used for BTR, BTT, or DT.

Thoratec Paracorporeal Ventricular Assist Device. The Thoratec paracorporeal VAD (PVAD) system is composed of a single chamber with a seamless polyurethane bladder housed in a rigid casing (Fig. 91-8, A).¹⁶⁰ VAD inflow cannulas are either atrial or ventricular. Outflow cannulas have a polyester graft attached for direct connection to the aorta or pulmonary artery, similar to the ABIOMED cannulas. Mechanical tilting disk valves at both the inflow and outflow connections ensure unidirectional flow and require anticoagulation. A pneumatic driveline is connected to the rigid casing and supplies alternating vacuum and pressure to facilitate bladder filling and emptying, respectively. The pump can be adjusted to accommodate changing preload and afterload.

The Thoratec PVAD is similar to ABIOMED but is more portable and has the potential for outpatient use in patients as a BTR or BTT.¹⁶⁰⁻¹⁶³ Two advantages to the Thoratec PVAD system are the ability of secure ventricular inflow (VAD) cannulation and the applicability of long-term utilization. LV cannulation provides better ventricular decompression than left atrial cannulation.¹⁶⁴⁻¹⁶⁸ This is important because LV distention or inadequate decompression will limit ventricular recovery in some patients. Ventricular cannulation also provides better VAD performance and reduces the risk of thrombotic complications, particularly in the setting of AMI.^{106,166-168} RV cannulation provides similar advantages over right atrial (RA) cannulation. However, these advantages may not be manifest if the tricuspid valve is left intact, because the tricuspid leaflets are often in close proximity to the cannulation tip and can obstruct VAD inflow.¹⁶⁹ In this situation, the advantages and disadvantages of RV versus RA cannulation must be weighed to direct the best approach.

As of July 2012, over 5000 Thoratec PVADs have been placed worldwide in 277 centers over the last 30 years.¹⁷⁰ More than half of the patients received biventricular support. Survival and hospital discharge rates vary widely between 20% and 80%, depending on the etiology of shock and the medical center.^{99,110,160,164,171-173} Cases of acute fulminant myocarditis with CS are among the best situations for VAD support with the Thoratec PVAD system, having an 88% recovery-with-discharge rate.⁹⁹ Complications of the Thoratec PVAD system are similar to other extracorporeal VAD systems when used for treatment of CS and include infection, stroke, bleeding, and acute renal failure. The rates of these complications vary among different series but range from 10% to 60%.^{160,164,171,172,174-178}

Thoratec Intracorporeal Ventricular Assist Device. Options for pulsatile intracorporeal long-term support include the Thoratec implantable VAD (IVAD) and Thoratec HeartMate XVE LVAD. The Thoratec IVAD is an implantable version of the Thoratec PVAD with identical internal components. The major difference is a smooth polished titanium housing that facilitates implantability (Fig. 91-8, B). Advantages of the IVAD over the PVAD are the decreased risk of infection due to the lack of cannulas exiting the skin and improved patient mobility.

HeartMate XVE LVAD. HeartMate XVE has a fully implanted pusher-plate blood pump with externalized drivelines (Fig. 91-9). It uses bioprosthetic porcine valves to ensure unidirectional flow. The HeartMate XVE has a flexible polyurethane diaphragm that pushes against a titanium alloy housing generating a maximum stroke volume of 83 mL. A unique feature of this device is the blood contact surface, which is textured with polyurethane fibrils on the diaphragm side and sintered titanium spheres on the housing. Fibrin and cellular components react and bond to the surface, creating a pseudointima, precluding the need for anticoagulation. Antiplatelet therapy is recommended.

FIGURE 91-8 ■ Thoratec ventricular assist system: a pneumatically powered system configured for uni- or biventricular support with paracorporeal (PVAD) and intracorporeal (IVAD) options. (A) Schematic demonstrating configuration for right and left ventricular support. (B) The IVAD (below) shown next to a PVAD (above). The smooth, contoured, polished titanium housing and the polyester velour-covered driveline allow for implantability with the IVAD. (From Hunt SA, Frazier OH. Mechanical circulatory support and cardiac transplantation. *Circulation* 1998;97:2079–2090. Copyright 1998, American Heart Association; Slaughter MS, Tsui SS, El-Banayosy A, et al. Copyright 2007, The American Association for Thoracic Surgery.)

HeartMate XVE was the first implantable device approved for both BTT and DT.¹⁷⁹ The landmark REMATCH (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure) compared the use of the HeartMate XVE versus optimal medical therapy in patients with New York Heart Association class IV HF who were not eligible for transplant.¹⁸⁰ Survival at 1 year was 52%

FIGURE 91-9 ■ The HeartMate vented electric left ventricular assist device (HeartMate XVE): an intracorporeal, electrically powered system. (A) Textured surface designed to reduce thrombogenicity. (B) Schematic demonstrating position of pump and related components. (From Loisance D. Mechanical circulatory support: a clinical reality. *Asian Cardiovasc Thorac Ann* 2008;16:419–431. Copyright 1998, American Heart Association.)

with the device compared to 25% with medical therapy ($P = 0.002$). Rates at 2 years were 23% and 8%, respectively ($P = 0.09$). Use of the device as also associated with significantly improved quality of life at one year.

Thoratec IVAD and HeartMate XVE both have variable modes that can generate fixed rates or demand-sensitive rates. Both are approved for use for the treatment of end-stage HF, but they may have a selective role for CS. These devices are practical alternatives for use in a “double-bridge” setting with initial resuscitation using a temporary device (i.e., ECMO/cardiopulmonary support or ABIOMED) for stabilization and pulmonary recovery.^{105,109,110,181,182} Results with these devices have been favorable and, in certain subsets of patients, better than longer term

FIGURE 91-10 ■ Implantable continuous-flow ventricular assist devices currently in clinical use: (A) MicroMed-DeBakey, (B) Jarvik 2000, (C) HeartMate II, and (D) HeartWare. support with other systems.^{99,177,183–188} Complications have been similar to other VADs and include bleeding, infection, stroke, thrombotic complications, and renal insufficiency.

CardioWest Total Artificial Heart (SynCardia TAH). SynCardia TAH is a pneumatic pulsatile pump used to completely replace cardiac function in cases of severe biventricular myocardial damage. It is indicated as a BTT and was first used successfully in 1985.¹⁸⁹ It is a large device that resides orthotopically within the pericardium. It has limited use in acute CS.

Continuous-Flow Left Ventricular Assist Devices

In the continued search for smaller, implantable LVADs with increased durability, there have been many advances in technology that have led to an array of continuous flow (nonpulsatile) pumps, each with unique features (Fig. 91-10).¹⁹⁰ These axial or centrifugal flow pumps are smaller and more durable than pulsatile devices, making them well suited for long-term support as a BTT, BTR, or DT.^{191–194} They are placed within the pericardium or in a preperitoneal pocket, with only an external driveline exposed to provide power and device control. These devices are relatively costly, provide isolated LV support, and require specialized training to implant. Consequently, they have not yet received widespread use for acute CS. However, they may be ideally suited as a bridge-to-bridge after resolution of the shock state with a temporary MCS device. These devices will continue to play a significant role in HF management and are briefly outlined.

HeartMate II (HMII). HeartMate II (Thoratec Corp.) is an implantable axial flow LVAD that has been used as a BTT and DT.^{191,195,196} The device is implanted in a preperitoneal pocket with the inflow cannula situated in the LV apex. Outflow is via a graft anastomosed to the ascending aorta. The device was approved for DT by the FDA in 2010. A prospective postapproval study confirmed the efficacy of the device and demonstrated a reduction in the median length of

stay by 6 days as compared to the pivotal DT trial.¹⁹⁷ Results of the recent ROADMAP trial were presented at the International Society of Heart and Lung Transplantation.¹⁹⁸ Functionally limited HF patients treated with the HMII LVAD had significant improvement in the primary outcome composite of survival and improvement in a 6-minute walk test at 1 year compared to similar patients treated with optimal medical therapy.

Jarvik 2000. Jarvik 2000 (Jarvik Heart Inc., New York, NY) is an implantable axial flow pump used as a BTT and for DT.^{193,199,200} It is unique in that the pump itself resides within the LV cavity, providing outflow via the LV apex to a graft anastomosed to the ascending or descending thoracic aorta. It is a DC battery-powered device, utilizing AC power only to recharge the batteries.

HeartWare Ventricular Assist Device (HVAD). The HVAD (HeartWare, Inc., Framingham, MA) is a centrifugal pump that is implanted within the pericardial space. The pump is attached directly to the LV apex where inflow is provided. Outflow is via a graft sewn to the ascending aorta. Based on results from the ADVANCE clinical trial, the HVAD has now received FDA approval as a BTT device.²⁰¹

DuraHeart. DuraHeart LVAS (Terumo Heart, Inc., Ann Arbor, MI) is a magnetically levitated centrifugal pump utilized as a BTT.²⁰² It is implanted in a preperitoneal pocket. Inflow is via a titanium conduit placed in the LV apex, and outflow is via a graft anastomosed to the ascending aorta. The inner surface is coated with covalently bonded heparin. Ambulation is improved with the use of battery power.

INCOR. The INCOR LVAD (Berlin Heart AG, Berlin, Germany) is an axial flow pump that is placed in a preperitoneal pocket. Inflow is via the LV and outflow via the ascending aorta. The device is powered via a percutaneous driveline that can use either AC or DC sources. The most experience with the Berlin Heart has mainly been in Europe. It has been used as a BTR, BTT, and for DT.²⁰³⁻²⁰⁵

Levacor. The Levacor VAD (Worldheart Corp., Salt Lake City, UT) is a centrifugal pump placed in a preperitoneal pocket. The outer surface of the inflow cannula is coated with titanium microspheres to create a textured surface that will encourage tissue in-growth and promote fixation within the LV. Outflow is to the ascending aorta. A percutaneous drive-line provides power and control to the pump. It is powered with either AC or DC power to increase ambulatory operation. Initial experiences with the pump have been favorable.^{194,206,207}

Synergy Micropump. The Synergy micropump (CircuLite, Inc., Saddle Brook, NJ) is a miniature axial flow LVAD that is only slightly larger than an AA battery. It is a partial LVAD designed to augment flow in patients with NYHA class IIIb or IV HF.^{208,209} It placed in a subcutaneous pocket on the right anterior chest wall. Inflow is from a graft sewn to the left atrium, and outflow is via a graft sewn to the right subclavian artery. The device is battery powered via a driveline that exists in the upper abdomen.

TREATMENT OF CARDIOGENIC SHOCK: AN ALGORITHM FOR MECHANICAL CIRCULATORY SUPPORT

The hallmarks of CS are low CO, hypotension, peripheral vasoconstriction, cold extremities, poor urine output, and altered mental status. As the pathophysiologic state progresses, pulmonary insufficiency and pulmonary edema ensue. Extrinsic causes of CS most commonly manifest as circulatory collapse secondary to pericardial tamponade. Acute tamponade is easily diagnosed by echocardiography and requires surgical or percutaneous evacuation and subsequent treatment of that which caused the tamponade (e.g., traumatic injury, aortic dissection, ruptured aneurysm). Extrinsic causes of CS usually require immediate surgical intervention but rarely necessitate mechanical assistance. However, intrinsic causes of CS can be refractory to both medical and surgical therapies and may require MCS. Intrinsic causes can be divided into four pathophysiologic classifications: (1) acute valvular insufficiency, (2) CSMI, (3) acute myocarditis, and (4) postcardiotomy

cardiac failure. Irrespective of the etiology of CS, the approach toward the initial management of patients should be fairly uniform. A suggested management algorithm is outlined in Figure 91-11.

First, insertion of a pulmonary arterial balloon catheter and echocardiography should be done to help formulate a differential diagnosis. Severe valvular insufficiency or a VSD can usually be effectively excluded at this juncture. If severe aortic insufficiency is present, chronotropic control (heart rate 80 to 100 beats/min) and afterload reduction with inotropic support should be the initial maneuvers. An IABP is contraindicated because aortic regurgitation will worsen; these patients should be prepared for immediate aortic valve replacement. For patients with acute MR or a VSD, an IABP should be placed immediately in conjunction with inotropic support and afterload reduction. Surgical intervention should proceed emergently. Cardiac catheterization is pursued preoperatively in order to identify coronary lesions that would require CABG only if the patient can be adequately stabilized.

Acute fulminant myocarditis usually presents in a previously healthy individual with no history of cardiac disease. Patients with presumed myocarditis who do not stabilize after the insertion of an IABP and concomitant inotropic infusion should be diverted to VAD support expeditiously. A remarkable percentage of these patients will recover if adequately supported during the acute phase of this disease. Short-term to intermediate-term VADs are optimal in these patients because of the ease of their insertion and removal and the anticipation for relatively short-term recovery. Giant cell myocarditis is one exception to this rule, because most patients with this diagnosis will require transplantation.²¹⁰⁻²¹³

CSMI requires pharmacologic support along with emergent cardiac catheterization and PCI as indicated. MCS can be rapidly instituted with IABP placement and should be considered in conjunction with PCI. If a mechanical complication (i.e., severe MR or VSD) has occurred, an IABP should be placed without delay. Urgent surgical intervention is usually required for these mechanical complications. The culprit vessel resulting in the AMI is treated immediately with PCI. The number of diseased arteries remaining and the clinical status usually determine subsequent allocation to further PCI or CABG. This can be accomplished several days later, once the myocardium is recovered and the shock state has resolved. Patients who remain in CS after AMI, despite PCI, IABP, and inotropic support, should be considered for VAD support.

Postcardiotomy CS should be managed intraoperatively with an initial trial of IABP and inotropic support. If there is persistent shock or an inability to be weaned from CPB, VAD implantation is the next therapeutic step, provided a meaningful recovery is predictable or a plan for transplantation or permanent therapy can be clarified. The general recommendation for implantation of a VAD for postcardiotomy failure is within 1 hour of the first failed attempt to wean from CPB.

The mode of MCS used for CS is determined by a number of factors. First is the degree of pulmonary insufficiency. If there is pulmonary failure with a very large alveolar-to-arterial oxygen gradient on maximal ventilatory support, ECMO support is indicated. A small percentage of ECMO patients in this setting will recover, some will require VAD placement as a BTT, fewer still will bridge to VAD and then to recovery. If the degree of pulmonary insufficiency is limited to pulmonary edema that is likely to recover with adequate CO, patients should undergo VAD placement directly. The choice of VAD in this situation is also dependent on several factors, including the predicted need for short- or longer term support, the need for univentricular versus biventricular support, the chance of ventricular recovery, the institutional experience with different devices, device availability, and the relative risks of anticoagulation.

The ABIOMED and Levitronix CentriMag systems are attractive options for postcardiotomy cardiac failure in those patients predicted to recover within days to a week of surgery, for cases when neurologic function is not known or is markedly compromised, and for patients who are not candidates for transplantation but may BTR or bridge to

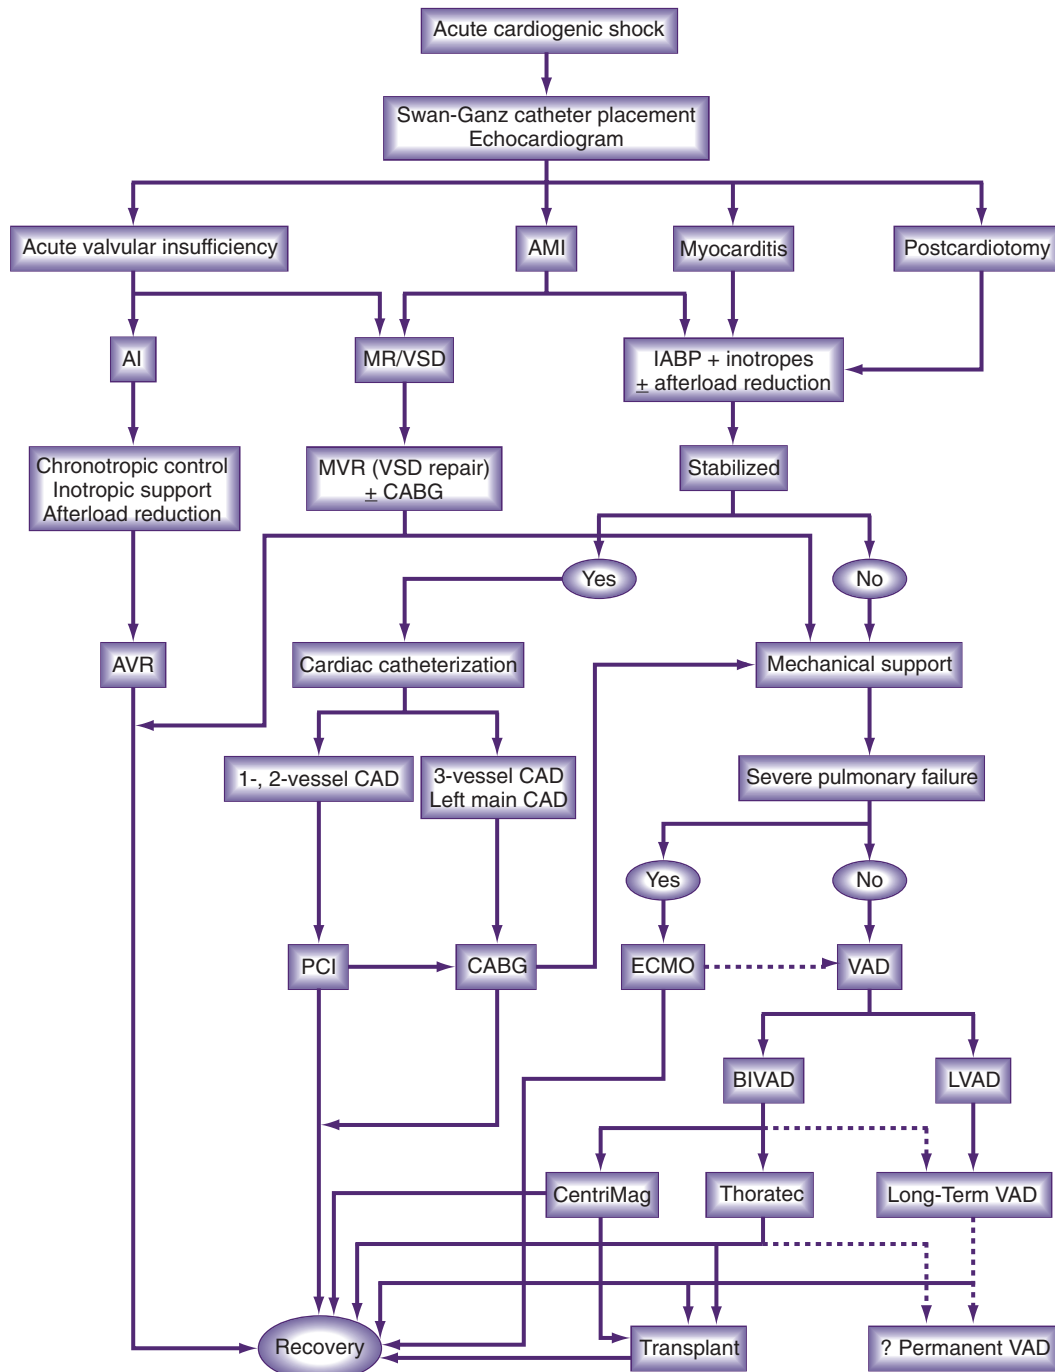

FIGURE 91-11 ■ Algorithm for the management of acute cardiogenic shock.

a long-term and ambulatory device once stabilized. Both are easy to insert. Therefore, in cases of profound CS when operative brevity is paramount, these devices may be beneficial. Additionally, both allow for atrial cannulation, which may make conversion to other long-term VAD systems technically easier.

The Thoratec PVAD system is the most versatile VAD and remains the support used most frequently for the treatment of refractory CS. The device is relatively easy to install, may be used for short-term or long-term uni- or biventricular support, and allows the potential for ambulation. VAD inflow cannulation can be either via the atria or ventricles. Ventricular cannulation is preferable even in the case of AMI because of its hemodynamic efficiency, reliability, and better ventricular decompression. Despite the friability of freshly infarcted

myocardium, the Thoratec ventricular cannulas are safe to insert through infarcted tissue. Once a patient is stabilized with the Thoratec system, a management strategy can be mapped out as BTR, BTT, or permanent therapy with an intracorporeal device.

Initial placement of implantable pulsatile or continuous-flow VADs (e.g., HeartMate XVE or HeartMate II) for MCS in patients with CS is generally not indicated. These devices may be used as a second bridge (“bridge-to-bridge”) toward recovery, BTT, or permanency. There may be a select group of patients in whom these intracorporeal VADs have a primary role in CS: (1) patients who require a larger CO than other devices can generate (large individuals needing a CO greater than 6 L/min to reverse the shock state); (2) patients who are more stable, can sustain longer operative times, and are unlikely to achieve myocardial

recovery; and (3) patients in whom anticoagulation is contraindicated, making the HeartMate XVE device potentially safer.

CONCLUSION

CS remains a lethal problem with a mortality rate as high as 75%.^{3,214,215} Patients who cannot be stabilized with inotropic support and an IABP should be considered for MCS with a VAD. The ideal assist device that can be easily placed, is versatile, portable, has minimal risk of complication, offers a normal CO with physiologically equivalent characteristics such as pulsatile flow, and is easily removed does not yet exist. Currently, there are three modes of MCS that have received widespread use in the patient population with CS, including ECMO/cardiopulmonary support, the ABIOMED AB 5000, and the Thoratec PVAD system. Implantable devices such as the HeartMate LVAS XVE and HeartMate II have occasionally been used in this moribund population but have a more defined role in the subacute and chronic HF population.

The use of MCS for acute CS has facilitated impressive improvements in survival for certain disease cohorts such as those with

acute myocarditis, with survival rates over 70%.⁹⁹ VADs have had less remarkable an impact on patients with postcardiotomy shock or CSMI,¹⁰⁶ but results in these patient populations are improving annually. Inherent to achieving better results is our understanding that patients who present with CS typically have significant underlying comorbidities with multiple-system organ dysfunction and marked derangements in both coagulation and inflammatory mediators that complicate management. They need to be approached by an integrated multidisciplinary team, including cardiologists, cardiac surgeons, anesthesiologists, critical care specialists, and experienced nursing staff to implement efficient and decisive treatment plans. These integrated systems offer the greatest chance for success. The future holds exciting promise with the rapid expansion of 3D printing technology, which is now capable of producing a titanium LVAD within a few hours. Transcutaneous energy transfer (TET) systems may someday obviate the need for percutaneous drive lines. As technologies expand and improve exponentially every year, it is clear that MCS will continue to play a pivotal role in the management of these difficult patients.

KEY POINTS

1. The leading cause of death among hospitalized patients with AMI continues to be CS. Mortality remains high at approximately 40%.
2. The hallmarks of CS and low CO are hypotension, peripheral vasoconstriction, cold extremities, poor urine output, and altered mental status.
3. Intrinsic causes of CS can be divided into four pathophysiologic classifications: (a) acute valvular insufficiency, (b) acute myocardial infarction, (c) acute myocarditis, and (d) postcardiotomy cardiac failure.
4. Echocardiography should be done to help formulate a differential diagnosis, and insertion of a pulmonary artery balloon catheter should be considered.
5. CSMI requires immediate cardiac catheterization. Concomitant IABP placement should be considered in addition to pharmacologic support.
6. Pioneering surgeons recognized by the 1960s that LV decompression and myocardial rest could afford enhanced cardiac recovery after the insult of open-heart surgery.
7. The physiologic rationale for the efficacy of the IABP includes (a) LV systolic unloading directly reduces stroke work, which in turn reduces myocardial oxygen consumption during the cardiac cycle, and (b) diastolic augmentation, which raises arterial blood pressure and provides better coronary arterial perfusion during diastole, yielding increased oxygen delivery to the myocardium.
8. The absolute indications for IABP placement include CS, uncontrolled angina pectoris, acute postinfarction VSD or MR, and postcardiotomy left-sided HF with low CO.
9. Relative contraindications to IABP use include severe atheromatous and atherosclerotic descending thoracic aorta, descending aortic aneurysm, recent descending thoracic aortic surgery, and mild to moderate aortic insufficiency.
10. IABP support, combined with revascularization, portends a better prognosis than adjunctive IABP use with medical therapy alone.
11. Short-term cardiopulmonary support for CS is as an important adjunctive therapy. It is a relatively simple means of establishing immediate and complete circulatory support, requiring no additional equipment other than that needed for standard cardiopulmonary bypass support during cardiac surgery.
12. Initial placement of implantable VADs (e.g., HeartMate) for MCS in patients with CS is generally not indicated. These devices are best suited as a bridge-to-bridge once the shock state has resolved, often with a temporary MCS device.

ANNOTATED REFERENCES

- Farrar DJ. The Thoratec ventricular assist device: a paracorporeal pump for treating acute and chronic heart failure. *Semin Thorac Cardiovasc Surg* 2000;12:243–250.
The experience with use of the Thoratec system through May 2000 is reviewed. The results of over 1300 implants are discussed. Survival rates among patients transplanted and weaned from the Thoratec VAD support were 86% and 59%, respectively.
- Hochman JS, Sleeper LA, Webb JG, et al. Early revascularization in acute myocardial infarction complicated by cardiogenic shock. SHOCK Investigators. Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock. *N Engl J Med* 1999;341:625–634.
Results from the randomized SHOCK trial are reported. Emergency revascularization did not significantly reduce 30-day mortality, but it did reduce mortality at 6 months, and IABP placement helped facilitate early revascularization.
- Pagani FD, Lynch W, Swaniker F, et al. Extracorporeal life support to left ventricular assist device bridge to heart transplant: a strategy to optimize survival and resource utilization. *Circulation* 1999;100:11206–11210.
Experience using ECMO for initial resuscitation and as a bridge to left ventricular assist device placement and subsequent heart transplantation in patients with severe hemodynamic instability is presented. ECMO can be used to salvage some survivors from this very high-risk cohort before the utilization of LVAD resources.

ANATOMY AND PHYSIOLOGY OF THE PORTAL SYSTEM

The term *portal system* refers to a venous system that begins and ends in capillaries. The portal venous system commences in the capillaries of the intestine and ends in the hepatic sinusoids. The portal venous system drains blood from the gastrointestinal (GI) tract, pancreas, gallbladder, and spleen. The portal vein originates from the confluence of the splenic vein and the superior mesenteric vein. The inferior mesenteric vein and short gastric veins drain into the splenic veins. The superior mesenteric vein drains all the blood from the small bowel and the right colon while the inferior mesenteric vein drains the blood from the remainder of the colon and most of the rectum. Flow in the portal vein is normally about 1 L/min (approximately 20% cardiac output) with a mean pressure of 7 mm Hg. Although the blood in the portal vein is the outflow from capillary beds and therefore has relatively low oxygen content, 70% of hepatic oxygenation is derived from the portal flow. The blood flowing through the hepatic artery supplies the remainder of hepatic oxygen consumption and is the primary blood supply to the biliary tree. The portal vein carries a high concentration of nutrients and hormones, facilitating the liver's central role in fat, carbohydrate, drug, and protein metabolism. Toxic substances are removed by hepatocytes, and bacteria (and bacterial products) are removed by Kupffer cells. Portal venous blood and hepatic arterial blood mix at the sinusoidal level, and there exists an adenosine-mediated local hepatic arterial autoregulatory "buffer response" that increases arterial inflow in response to low portal flow; however, the total hepatic flow is decreased. This buffer response is also dysregulated in sepsis.

Postsinusoidal blood drains through hepatic venules into hepatic veins and then into the inferior vena cava to return to the systemic circulation. A variety of pathologic processes can result in portal venous flow becoming "obstructed." Regardless of the cause (i.e., intra- or extrahepatic obstruction), this resistance to portal flow increases portal pressure and leads to the development of what is called the *portal hypertension syndrome*, which is characterized by the formation of portosystemic collaterals. Under these circumstances, only a portion of the blood flow that originates within the portal system reaches the liver; the remainder is diverted through collaterals and enters the systemic circulation directly.

In the setting of portal hypertension, collaterals will often form. The major sites of collateral remodeling are in the gastroesophageal region. Most commonly, these vessels, often called varices, form between the inferior mesenteric vein and the hemorrhoidal vein, at the umbilical vein, and along the anterior abdominal wall. Of note, collateral vessels may also develop at the sites of previous or current colostomy stomas, in which case they are termed ectopic varices. In addition to the formation of discrete collateral vessels, there are also more generalized changes within the GI tract, leading to vascular ectasia or portal hypertensive enteropathy. Bleeding may result from varices or portal hypertensive enteropathy.

Patients with portal hypertension exhibit characteristic splanchnic and systemic circulatory changes. The key to these manifestations is abnormal vasodilation. Decreased arteriolar tone in the splanchnic vessels leads to splanchnic hyperemia and hypervolemia but also a reduction in effective central blood volume, with the majority of the

excess blood volume residing within the splanchnic bed. These circulatory changes prompt systemic homeostatic responses, with activation of the vasoconstrictor and sodium-retaining mechanisms. Overall, these changes comprise a hyperdynamic circulation characterized by increased cardiac output and heart rate to maintain blood pressure despite decreased systemic vascular resistance, with an overall increase in total plasma volume.

THE PATHOPHYSIOLOGY OF PORTAL HYPERTENSION

The primary pathophysiologic derangements in portal hypertension can be expressed by Ohm's law, $V = IR$, where V is pressure, I is flow, and R is resistance. This equation demonstrates that with increased resistance and stable flow, pressure must increase. In portal hypertension, this is complicated by multiple other general derangements and alterations in homeostasis. Moreover, as the compensation for portal hypertension ensues, splanchnic blood flow increases along with increased resistance, adding to the elevated portal pressure. In addition to these mechanical forces on the portal vessels, when liver disease is involved, a reduction in synthetic capacity of the liver leads to decreased albumin synthesis and subsequent decreased total intravascular oncotic pressure. Combined with hyponatremia, these factors further contribute to increased portal pressures. In the setting of cirrhosis, animal data reveal there is an intrahepatic component of the portal resistances that is dynamic and consists of a constrictive and fibrogenic phenomenon that is associated with the alterations in hepatic stellate cells.¹ Various vasoactive substances and neurohormones further influence this system, adding more components to portal hypertension. Further details are beyond the scope of this review. [Table 92-1](#) summarizes some of the basic pathophysiologic findings of cirrhosis and portal hypertension.

DIAGNOSIS OF PORTAL HYPERTENSION

PHT is defined as a portal pressure that is 5 mm Hg greater than the pressure measured in the inferior vena cava or a pressure of more than 15 mm Hg in the splenic vein or portal pressure measured at surgery. If the gradient is greater than 10 mm Hg, then clinically significant PHT is present. The direct consequences of PHT are the formation of portosystemic collaterals and splenomegaly. Portosystemic collaterals can become clinically apparent as gastric or esophageal varices, umbilical vein recanalization, retroperitoneal collaterals, and rectal or ileostomy varices. The complications of PHT are variceal bleeding, gastropathy, hyperdynamic circulation, ascites, hepatic hydrothorax, hepatorenal syndrome (HRS), hypersplenism, and hepatic encephalopathy. The most clinically significant complication will be discussed in the sections to follow. Varices are rarely seen if the gradient is less than 10 mm Hg. Variceal bleeding is not observed if the pressure gradient is less than 12 mm Hg, and protection from variceal bleeding is gained if the pressure gradient can be manipulated to less than 12 mm Hg or a 20% reduction in pressure is achieved.

Direct measurement of the hepatic vein wedge pressure of the portal venous pressure requires invasive means, most often transjugular catheterization. The advantage of this approach is that caval and hepatic venous pressures can be measured during the same procedure.

Less frequently, a transhepatic approach is directly (by cannulating a branch of the superior mesenteric vein) at the time of a surgical procedure. Very rarely, splenic pulp pressure is measured.

Indirect measurements also can be used to assess the portal pressure gradient. This procedure involves measurement of the free and wedged hepatic venous pressure using catheterization of the right hepatic vein. Wedged hepatic venous pressure (measured using a balloon-tipped catheter) reflects the pressure in a static column of blood from the hepatic vein to the sinusoid. It is an assessment of sinusoidal pressure rather than portal venous pressure and therefore may underestimate the portal pressure gradient in disease states

TABLE 92-1 Pathophysiologic Changes in Portal Hypertension

| PATHOPHYSIOLOGIC CHANGE | SPECIFICS |

| Decrease in NO, CO | |

characterized by presinusoidal hypertension. The free hepatic venous pressure is obtained with the catheter in the hepatic vein and gives an assessment of caval pressure. Free hepatic venous pressure is not elevated in patients with diseases characterized by presinusoidal and sinusoidal PHT, but it is characteristically raised in posthepatic (or extrahepatic postsinusoidal) etiologies. The gradient between the two measurements is called the *hepatic venous pressure gradient* and is the most commonly quoted parameter in the medical literature regarding the management of PHT. Both the absolute value of the hepatic venous pressure gradient and the change in the hepatic venous pressure gradient with pharmacotherapy have prognostic significance related to the risk of variceal bleeding. It is important to understand the true definitions of these various pressures so that the data obtained from the various measurements can be properly interpreted. If the proceduralist is less familiar with the nuances and meaning of the values obtained, incorrect conclusions will be drawn. In the [Table 92-2](#), we list some of the most common etiologies of portal hypertension classified by site of increased resistance.

GI BLEEDING

GI bleeding can always be life-threatening in the critical care setting. However, this is especially true when cirrhosis and portal hypertension exist. The causes of GI bleeding are many, and we will restrict the discussion to the more common scenarios. In the diagnostic and therapeutic algorithms, acute bleeding in decompensated chronic liver disease usually associated with cirrhosis can present as upper or lower GI bleeding. Although the diagnostic algorithms are similar for GI bleeding in the presence or absence of cirrhosis, the etiologies by percentage vary considerably. The chart below ([Fig. 92-1, A](#)) demonstrates this variability. In general, 73.2% of all patients presenting with GI bleeding in the ER will be noncirrhotic, and 26.8% will be cirrhotic. Of note, in cirrhotic patients, approximately 50% of all bleeding will be secondary to esophageal varices whereas in noncirrhotics, bleeding is most commonly due to bleeding gastric ulcers ([Fig. 92-1B](#)).

GI bleeding in the portal hypertensive patient most often is found by the observation of melena and/or hematemesis in combination with a dropping hematocrit and possibly hemodynamic instability. Most would recommend the initial placement of a nasogastric tube to determine, if, in fact, the seemingly obvious source is an upper GI bleed. This should be simultaneously accompanied by a request for and

TABLE 92-2 Etiology of Portal Hypertension Grouped by Location of Insult

| SITE OF INCREASED RESISTANCE | CONDITION | FHP | WHVP | HVPG | SPP |
|--|---|------------|-------------------|-------------------|------------|

preparation for upper GI endoscopy. Of note, in the critical care setting, some assumed upper GI bleeding episodes can actually be from another site of bleeding and not truly from the upper GI tract. In other words, the critical care practitioner must not miss another source of bleeding that is masquerading as an upper GI bleed. Most notably, bleeding can come from the soft palate hemoptysis, the sinuses, or the nasopharyngeal region. GI bleeding may also manifest as esophageal necrosis or perforation, possibly associated with previous banding therapy, and may only manifest with subtleties (e.g., pneumomediastinum). Therefore, there must be a heightened level of suspicion in patients who have a history of these typically routine interventions. Hemobilia is another rare consequence of hepatic interventions, such as a transjugular intrahepatic portosystemic shunt (TIPS) procedure, endoscopic retrograde cholangiopancreatography (ERCP), or liver biopsy in a cirrhotic patient, which can present as a massive upper GI bleed.

Upper GI bleeding is diagnosed in the majority of cases with endoscopy, and immediate therapeutic options are available. Importantly, a secure airway must be in place before attempting endoscopy in critically ill patients. Endoscopic intervention options include epinephrine injection, thrombin injection, and thermocoagulation for ulcers or Dieulafoy lesions. For variceal bleeding, therapeutic maneuvers include banding, endoclips, sclerosants, and thrombin injections. Complications of endoscopy therapy include aspiration, side effects from sedation, perforation, and increased bleeding while attempting a therapeutic intervention.

The next diagnostic opportunity is usually the visceral angiography. This is often prompted by ambiguous findings on endoscopy or the

inability to implement control of the hemorrhage. In many institutions, CT angiography has replaced direct angiography as the initial diagnostic maneuver and has been shown to be more sensitive. A tagged red blood cell scan can often direct the therapy for slower bleeding emanating distally to the ligament of Treitz (Table 92-3).

Hemodynamic instability, especially from upper GI bleeding in the cirrhotic patients, may require additional aggressive interventions. Therapeutic maneuvers such as the Blakemore tube may be employed, even empirically. If there is a history of hemorrhage or an unknown presence of varices in a patient, this can often be lifesaving. Of course, a mechanical means to address hemorrhage would be accompanied by medical management. Medical management of GI bleeding is extensively reviewed in the references.²⁻⁵ In brief, pharmacologic therapy can assist in reducing GI hemorrhage via the vasoconstrictors, nonselective beta-blockers, and vasodilators that are listed in Table 92-4.

An important concurrent consideration for the situation of GI bleeding is that end organ perfusion is often limited not only to hypovolemia but also possibly by myocardial ischemia. Furthermore, the untoward consequences of a further reduction in perfusion, by whatever etiology, may further deteriorate the compromised hepatic function in a cirrhotic patient.

Therapeutic considerations and diagnostic maneuvers in an unstable patient should also be coupled with simultaneous therapeutic interventions in the critical care setting. Importantly, because the treatment modalities available will figure prominently in the algorithm for the proper care of upper GI bleeding in the setting of portal hypertension,

TABLE 92-3 Sensitivity and Specificity of Various Diagnostic Modalities³

| | SENSITIVITY | SPECIFICITY |
|----------------------|-------------|-------------|

TABLE 92-4 Medications Used in the Setting of Upper GI Bleeding to Achieve Hemostasis

| DRUG CLASS | MECHANISM OF ACTION | EXAMPLES |
|-----------------------------|--|--|
| Splanchnic vasoconstrictors | Produce splanchnic vasoconstriction and reduce portal venous inflow | Vasopressin Terlipressin Somatostatin Vaptreotide |
| Nonselective beta blockers | Reduce hepatic venous pressure gradient via systemic hypotensive effect | Propranolol |
| Venodilators | Decrease intrahepatic and/or portocollateral resistance | Isosorbide mononitrate |
| Antifibrinolytic agents | Reduce the degradation of fibrin by slowing the conversion of plasminogen to plasmin—supporting clot formation | Tranexamic acid |

it is critical to involve interventional radiology early during treatment. Below is a chart that provides a brief algorithm for each diagnostic entity (Fig. 92-2).

Beyond the control of the hemorrhage, the overriding goal involves decompressive strategies to treat the underlying etiology of the hemorrhage. The TIPS procedure is on a continuum of the therapeutic maneuvers that eventually include complex surgical shunts to decompress portal pressure. As experience grows with the procedure and the safety margins increase, TIPS has become a mainline approach to primary portal decompression. As with any portal decompression procedure, a reduction in total hepatic blood flow with an associated reduction in hepatic function is always a major concern. Indications, contraindications, and complications of the TIPS procedure are considered in Table 92-5.

In acute variceal hemorrhage, efforts must be directed primarily at the control of hemorrhage. Conditions may exist that favor surgical portosystemic decompression over a TIPS placement. Portal vein thrombosis with a patent supermesenteric vein, known tumor within the liver in the path of a TIPS, and a technically unfavorable anatomy are common examples of when a surgical intervention is a preferred option. A mesocaval shunt is a good choice to create nonselective portosystemic decompression and control bleeding. The operative management of patients with the coagulopathy and severe portal hypertension should involve a surgeon experienced in a liver transplantation and hepatobiliary surgery.

Antibiotic therapy and proton pump inhibitors (PPI) are important adjuncts in cirrhotic patients with acute upper GI bleeding as they are at a high risk of developing severe bacterial infections (e.g., spontaneous bacterial peritonitis). The use of short-term prophylactic antibiotics (e.g., ceftriaxone) in patients with liver disease and GI hemorrhage has been a show to decrease the rate of bacterial infection and to improve patient survival. A Cochrane collaboration meta-analysis of 2223 subjects assessed the use of PPI in the setting of upper GI bleeding

in cirrhotic patients. Although there was no statistically significant difference in the outcomes of rebleeding, need for surgery, or mortality, those receiving up-front high-dose PPI therapies had a significantly reduced rates of high-risk stigmata identified at endoscopy and thus reduced the need for intervention at the time of endoscopy.³

In summary, portal hypertension can be associated with bleeding and can be a distinct challenge in the critical care environment. As we recommended earlier, the ultimate goal should be toward a definitive therapy. Commensurate with the magnitude of the hemorrhage, it is stressed that simultaneous activation of multidisciplinary diagnostic and therapeutic strategies will facilitate the best patient outcome. In the cirrhotic patient, liver transplantation is often the only definitive treatment. Efforts to preserve candidacy should be at the forefront of the critical care team's thinking as ultimately this strategy may be required for the life-saving outcome.

ASCITES

Another frequent consequence of portal hypertension is the development of ascites. Although it is not usually immediately life-threatening, it can significantly complicate the management of the intensive care unit (ICU) patient. The risk of developing ascites is 6% at 10 years with cirrhosis.

The differential diagnosis of ascites is usually clarified to the calculation of an albumin ascites gradient. A gradient of greater than 1.1 is consistent with portal hypertension, congestive heart failure (CHF), or Budd-Chiari syndrome. A gradient of less than 1.1 is consistent with carcinomatosis, tuberculosis, pancreatitis, serositis, or nephrosis. In portal hypertension associated with cirrhosis, systemic and splanchnic circulation is vasodilated, but renal blood flow is compromised and renal cortical blood flow is shunted to the medullary region of the kidney. These changes lead to a gradual increase in renal sodium and water retention. Thus, ascites contributes to a confusing physiologic state in which patients have excess body sodium but an even greater excess of free water and thus serum hyponatremia. Renal physiology acts as if the patient is intravascularly depleted and alterations in aldosterone metabolism simultaneously add to the sodium retention. Once the pressure of ascites increases in the abdominal compartment, it further compromises renal blood flow due to venous compression. All this creates a vicious cycle that complicates this syndrome. The mainstay of medical management of ascites is a reduction of sodium balance using dietary sodium restriction, free water restriction, and diuretics. Loop diuretics such as furosemide will interfere with sodium reabsorption while potassium-sparing diuretics can further increase sodium excretion, renal functioning permitting. Monitoring the serum albumin levels and giving albumin replacement when the level is below three are advised strategies to enhance control of ascites, as it may assist in increasing oncotic pressure. Newer medical strategies that may be considered for the control of ascites include midodrine, terlipressin, and vasopressin V2 receptor antagonists. Midodrine is an alpha adrenergic receptor agonist that results in an increase in mean arterial pressure in cirrhosis. Terlipressin is a vasopressin analog that acts on the V1 receptor in the splanchnic vasculature to cause splanchnic vasoconstriction, therefore decreasing splanchnic inflow and lowering the portal pressure. These improvements in systemic hemodynamics have been successfully used in the treatment of HRS in cirrhosis. Vasopressin V2 receptor antagonists (vaptans) are agents that compete with vasopressin for attachment onto the V2 receptors at the renal collecting duct to inhibit water reabsorption at that site, thereby inducing an aquaresis and reduced serum water content. There has been evidence that vaptans are also able to reduce the extent of ascites in cirrhotic patients.⁷

In the ICU setting, the baseline therapies for ascites in the cirrhotic patient can create acute alterations and electrolyte abnormalities associated with acute compromised hepatocellular function and acute renal injury. Therefore, it is not uncommon that medical management of ascites must give way to acute mechanical management, such as paracentesis or a TIPS procedure. Each of these procedures must

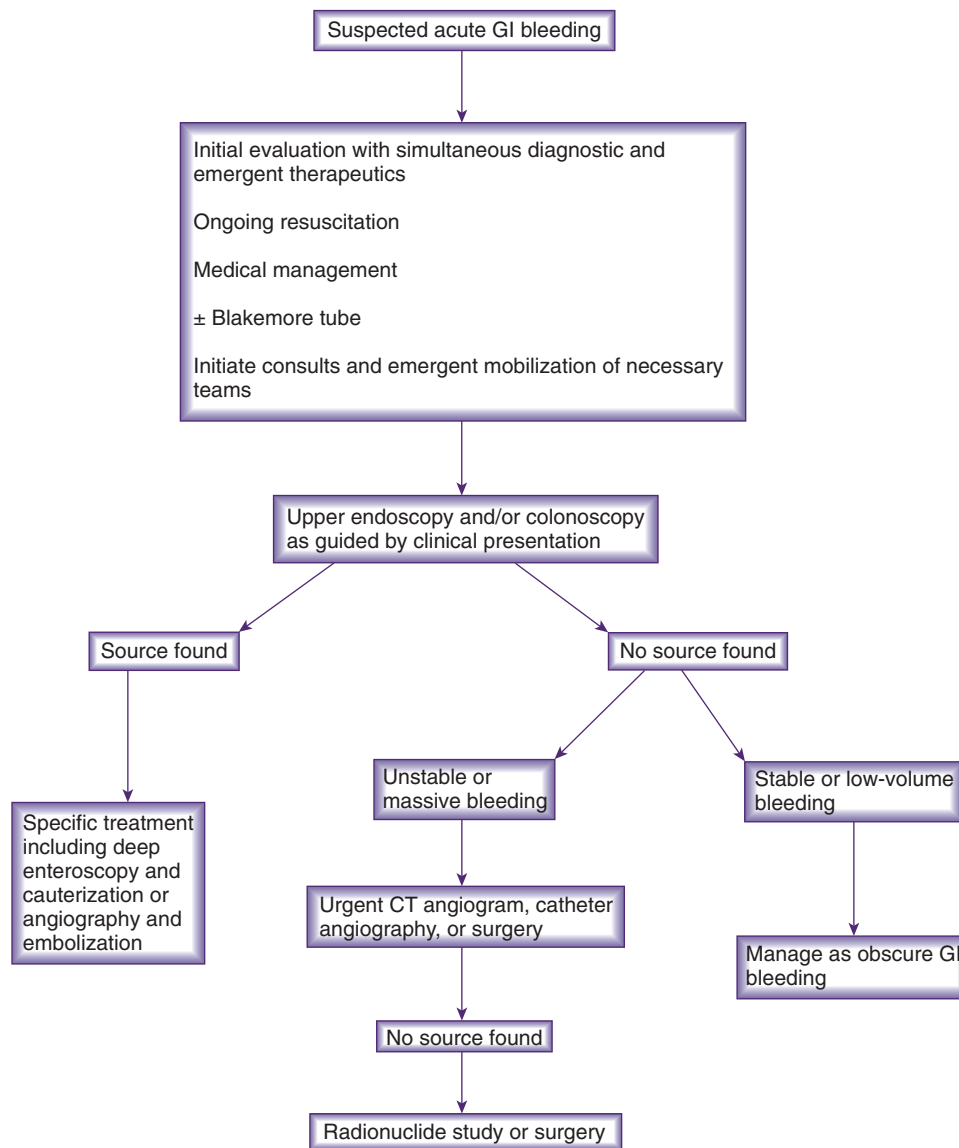

FIGURE 92-2 ■ The proper care of upper gastrointestinal bleeding in the setting of portal hypertension. The algorithm shows each diagnostic entity.

be correlated with the risk-benefit ratio associated with their complications.

As with all complications of portal hypertension, the goal of management is often to create an opportunity window for orthotopic liver transplantation.

■ HEPATIC HYDROTHORAX

Hepatic hydrothorax is defined as a significant pleural effusion greater than 500 mL, associated with cirrhosis and no primary cardiac or pulmonary disease. Pleural effusion is a result of either the increased formation of pleural fluid or decreased absorption of hepatic hydrothorax in which large volumes of fluid from the abdomen are transferred to the pleural space. The defects in the diaphragm are usually associated with the lymphatic fenestra but may also be due to larger defects, such as an iatrogenic injury to the diaphragm. Hepatic hydrothorax occurs most commonly on the right side and is associated with the bare area of the right triangular ligament. The negative pressure of the thoracic cavity favors a unidirectional flow of ascites from the abdomen to the chest. Once a hepatic hydrothorax occurs, it rarely

subsides and thus is considered an agonal finding associated with the end-stage liver disease. Based on the data presented involving 77 patients by Badillo et al. in 2014, patients with hepatic hydrothorax may have worsened outcomes than would be predicted by their MELD score alone. The patients in this study met the criteria of a known diagnosis of cirrhosis, pleural effusion, and pleural fluid consistent with the known characteristics of hepatic hydrothorax and not of an infection, malignancy, or other etiologies. The data suggest that some patients with hepatic hydrothorax die from complications arising from their pulmonary disease rather than from liver failure. The overall outcome of the patients was poor, with approximately half of the patients dying within one year of presentation. Patients who underwent TIPS procedure or liver transplantation had substantially longer periods of survival (Table 92-6).⁸

The diagnosis of hepatic hydrothorax is based on medical history, physical exam, pleural fluid analysis, and radiographic imaging. Pleural effusions associated with ascites are consistent with abdominal ascites and thus are, transudative. The cell count is low, and the total protein concentration is less than 2.5 g/dL. Typically, the serum to pleural fluid albumin gradient is greater than 1.1 g/dL, similar to the high serum to

TABLE 92-5 Indications, Contraindications, and Complications of the TIPS procedure⁶

ascites fluid albumin gradient seen in cirrhotic ascites. It should be noted that the hepatic hydrothorax can also be associated with more complex fluid collections in the chest (such as empyema), which may be spontaneous in nature or associated with prior infections of the pleural space. The etiology of empyema in the setting of hepatic hydrothorax is not completely understood.

The primary reason hepatic hydrothorax represents such a difficult treatment dilemma is the risk of converting the hydrothorax to an empyema with iatrogenic manipulation. Repeated thoracentesis should always be preferred over a chest tube. This is because the chest tube removal may be difficult to achieve, and the risk of contamination with leaving it in place is very high. Generally, no more than 2 L of pleural fluid should be removed to avoid pulmonary edema from lung expansion. Therefore, controlling the ascites becomes a very high priority for controlling the hepatic hydrothorax. The principles of managing the hepatic hydrothorax are similar to those presented in the ascites section but are more acute. Lung collapse associated with a substantial hepatic hydrothorax puts the patient at a high risk for a parenchymal lung infection.

Whereas thoracentesis is the preferred method over pigtail or chest tube thoracostomy, empyema may still result. This, of course, is catastrophic in the setting of end-stage liver disease. Ultimately, as in many of the complications of portal hypertension, a liver transplant is the only successful therapy since hepatic hydrothorax represents severe decompensation and, thus, is appropriately considered an agonal finding.

HEPATORENAL SECTION

HRS is defined as a functional renal failure in patients with liver failure and portal hypertension. The clinical scenario is usually one of acutely decompensated chronic liver failure and cirrhosis or in the setting of acute liver failure. The profound changes in renal physiology associated with liver failure are quite predictable, and thus renal dysfunction associated with changes in creatinine clearance are incorporated into the MELD (model for end-stage liver disease) score that is used for liver transplant allocation.

In this syndrome, the kidneys are morphologically intact; however, there are functional abnormalities resulting from renal cortical medullary blood flow derangements, which in turn can cause increases in afferent arteriolar resistance in the renal cortex. This results in renal cortical hypoperfusion and excessive sodium absorption in the tubular medullary areas of the kidney. Aldosterone metabolism and alterations in the renin-angiotensin axis, as well as multiple mechanisms that support vasoconstriction, further exacerbate the pathophysiology. Furthermore, systemic peripheral vascular resistance and splanchnic vasodilation associated with the shunting of the cirrhotic state result in lower mean arterial pressure and gross reduction in renal perfusion.

There are two types of HRSs: (1) type I reflects a more rapid change in renal function; and (2) type II occurs more slowly and is associated with a more insidious decline in hepatocellular function. In type I HRS, serum creatinine doubles over a 2-week interval and is usually greater

than 2.5. In type II HRS, the serum creatinine does not exceed 1.3 and may not have changed but may be associated with mild oliguria. The median survival is 2 weeks and 6 months for type I and type II HRS, respectively. Although there is no single test to definitively diagnose HRS, it should be suspected with a creatinine clearance less than 40 mL per minute, oliguria less than 500 mL per day, urine sodium less than 10 mEq, and serum sodium at less than 130 mEq with urine osmolality being greater than the plasma.

The prevalence of HRS in patients with ascites and cirrhosis is 18% and 39% at 1 and 5 years, respectively. In light of the above changes in pathophysiology, it is not surprising that patients who present with ascites can also have such complications such as hemorrhage, hyponatremia, and worsening encephalopathy. Precipitating factors associated with acute HRS include bacterial infections (57%), hemorrhage (36%), and therapeutic paracentesis with hypovolemia (7%).⁹

The treatment of HRS begins with the elimination of any factors that might be compromising hepatocellular function, such as systemic infection or GI bleeding. All medications should be reviewed for their risk-benefit ratio as it relates to exacerbation of renal toxicity. Vasoconstrictors may be of a transient benefit as well as beta-blockers to reduce splanchnic vasoconstriction. The TIPS procedure also may be useful as it will improve renal function and cirrhosis by decreasing sympathetic tone and thus increasing renal blood flow. In the sense that HRS is a complication of portal hypertension, the underlying cause of liver dysfunction is always best treated with liver transplantation in otherwise qualified candidates.

LIVER TRANSPLANT

As has been emphasized in this chapter, liver transplantation is the ultimate tool to treat portal hypertension. This procedure not only treats portal hypertension but also the source of portal hypertension, liver cirrhosis, as well. Without the option of liver transplantation, 5-year survival of patients with Child C cirrhosis and variceal bleeding is approximately 25%, whereas the 5-year survival after a liver transplant is as high as 75%.⁹ With too many listed patients waiting for too few deceased liver donors, not all patients who qualify for a liver transplant will receive a liver. The indication, listing, and timing of a transplant are complex and must be conducted by a complete liver transplant team. The etiology of liver disease, medical and surgical history, and

social circumstances are all part of the evaluation process. Upon listing, the patient will have a MELD score listed in UNOS DonorNet. It is a dynamic score based on a complex equation using lab values of INR, total bilirubin, and serum creatinine. The score is truncated at 40. There are share systems in place by region. Additionally, there is a discussion of incorporating serum sodium into the MELD score to achieve the fairest allocation of livers to the sickest patients first. The ability to assess when these severely ill patients are ready for a liver transplant is difficult. Contraindications to liver transplantation include active infection, extrahepatic malignancy, or a new malignancy. Other factors that may warrant ICU admission are not necessarily contraindications. Of course, the primary focus of critical care management for a listed transplant patient is to optimize the patient for transplantation.

KEY POINTS

1. Portal hypertension is defined as the presence of a raised portocaval pressure gradient that leads to many subsequent physiologic abnormalities.
2. Gastrointestinal bleeding is the most life-threatening complication of portal hypertension, and its treatment requires expedited multidisciplinary assessment and treatment.
3. Ascites, hepatic hydrothorax, hepatorenal syndrome, and hepatic encephalopathy are other complications of portal hypertension that require prompt recognition and expert medical and sometimes therapeutic intervention.
4. In cases in which liver disease, or even more important, cirrhosis, is involved, the complications of portal hypertension and a critical illness of the patient will be magnified.
5. Liver transplant should always be an underlying consideration and the potential goal for those with liver cirrhosis and portal hypertension as this will provide the ultimate and best treatment.

An association between advanced liver disease, ascites, and renal failure described in 1861 was named *hepatorenal syndrome* (HRS) by Helvig and Schutz in 1932.¹ HRS is a functional form of renal failure without renal histologic changes.² HRS is characterized by intense renal vasoconstriction, impaired renal perfusion, and low glomerular filtration rate (GFR) in the setting of splanchnic and systemic vasodilation.³ Among advanced cirrhotics, the incidence of HRS is 18% within 1 year and up to 40% at 5 years.^{4,5} The variability in the incidence is related to the degree of liver dysfunction, with higher Model for End-stage Liver Disease (MELD) scores portending an increased risk. HRS heralds a poor prognosis, with nearly half of the patients with HRS type 1 (HRS-1) dying within 2 weeks.^{4,6}

RENAL DYSFUNCTION IN CIRRHOSIS

Renal dysfunction in the setting of cirrhosis is common and is associated with adverse outcomes.^{7,8} The MELD system was implemented in 2002 to prioritize patients for liver transplantation with renal dysfunction weighted heavily. This has led to an increase in the number of patients with renal dysfunction undergoing liver transplantation.⁹ While HRS is the focus of this chapter; there may be other causes of acute kidney injury (AKI) in patients with cirrhosis. Common causes of prerenal AKI include the use of diuretics, lactulose, and hypovolemia. Intrinsic etiologies of AKI include glomerulonephritis, acute interstitial nephritis, and acute tubular necrosis.¹⁰ The etiology of renal disease is independently associated with prognosis, with HRS having the lowest 3-month probability of survival.¹¹

Several consensus definitions of AKI have been formulated. In 2004, the Acute Dialysis Quality Initiative (ADQI) group proposed the risk, injury, failure, loss of kidney function, and end-stage kidney disease (RIFLE) criteria, which categorized renal dysfunction into grades of increasing severity based on urine output and changes in serum creatinine.¹² Given that even small increases in serum creatinine can reflect kidney injury and adverse outcomes, the Acute Kidney Injury Network (AKIN) criteria were proposed in 2007 (Fig. 93-1).¹³ AKI defined by the RIFLE criteria is predictive of adverse outcomes in patients with cirrhosis.^{14,15} The 8th International Consensus Conference of the ADQI group agreed to apply the modified RIFLE criteria to define AKI in patients with cirrhosis, irrespective of the cause of AKI.¹⁶ At this time, it is unclear whether AKIN or classical HRS criteria better predict prognosis.^{17,18,19} There is evidence that smaller increases in serum creatinine are associated with poor outcomes.²⁰ Patients with the same pathophysiologic derangements of HRS who do not meet criteria may also benefit from treatment.

PATHOGENESIS OF HRS

Low blood pressure, a very low GFR (<40 mL/min), as well as an increase in plasma levels of renin, norepinephrine, and antidiuretic hormone characterize HRS.² The increase in shear stress in the splanchnic vasculature is a result of portal hypertension leading to the overproduction of nitric oxide and other vasodilators.²¹ Other factors contributing to splanchnic vasodilation include increased bacterial translocation, mesenteric angiogenesis, and hyporesponsiveness of the splanchnic vasculature to vasoconstrictors.²²

Sodium retention, impaired free-water excretion, and decreased renal perfusion and glomerular GFR are the main abnormalities in

HRS and are progressive. The first abnormality is the reduced ability to excrete sodium secondary to mineralocorticoid effects. As the disease progresses, patients are unable to excrete the sodium ingested in their diet, and ascites develops. When renal sodium avidity is extremely high, the plasma renin activity and the plasma concentrations of aldosterone and norepinephrine are elevated.^{23,24} Circulatory dysfunction is greater at this stage, with increased activity of the sympathetic nervous and the renin-angiotensin systems.

Renal perfusion and GFR are dependent on increased renal production of prostaglandins. These lipid mediators are vasodilators that antagonize the vasoconstricting actions of angiotensin II and norepinephrine. A syndrome indistinguishable from HRS can be produced in patients with cirrhosis, ascites, and increased plasma renin activity if prostaglandin synthesis is inhibited by nonsteroidal antiinflammatory drugs.^{24,25}

Peripheral arterial vasodilation has been implicated in HRS but primarily affects the splanchnic arterial vascular bed. Doppler ultrasonography studies demonstrate vasoconstriction in renal, brachial, femoral, and cerebral beds.^{26,27} Several endogenous vasodilators have been implicated in splanchnic vasodilation, including nitric oxide, carbon monoxide, glucagon, prostacyclin, and endogenous opiates.²⁸⁻³⁰

End-stage liver disease is associated with reduced systolic and diastolic response to stress, enlarged cardiac chambers, and repolarization changes, termed *cirrhotic cardiomyopathy*.³¹ The development of HRS has been associated with a lower arterial pressure, a marked decrease in cardiac output, and increases in plasma renin activity and plasma norepinephrine³² (Fig. 93-2).

DIAGNOSIS

In 2006, the International Ascites Club updated the diagnostic criteria for HRS,^{33,34} requiring a serum creatinine greater than 1.5 mg/dL in the absence of other potential causes of renal failure (Table 93-1).³⁵ However, it is possible to develop HRS superimposed on kidney injury of other etiologies.¹⁶ The first step in the diagnosis of HRS is a demonstration of elevated creatinine, which greatly underestimates the GFR in advanced cirrhosis.^{2,36} Similarly, urea is synthesized by the liver, and urea synthesis may be reduced as a consequence of hepatic insufficiency.^{37,38} Many patients may not meet the diagnostic criteria for HRS yet have significant renal injury similar to HRS.³⁹

CLINICAL TYPES

HRS is classified into two types according to the severity and form of presentation of renal failure.³⁴ HRS-1 is characterized by severe and rapidly progressive renal failure and defined by doubling of the serum creatinine concentration to 2.5 mg/dL in less than 2 weeks. HRS-1 is often precipitated by an infection, hemorrhage, paracentesis, surgery, or acute hepatitis. The association of HRS and spontaneous bacterial peritonitis (SBP) has been carefully investigated.⁴⁰⁻⁴² HRS-1 develops in approximately 30% of patients with SBP despite rapid and successful treatment. Patients with an intense systemic inflammatory response and high cytokine levels in plasma and ascitic fluid are especially prone to develop HRS-1 after infection. HRS-1 has a 2-week median survival.

HRS-2 is characterized by a more moderate and steady decrease in renal function, with a serum creatinine >1.5 mg/dL that fails to satisfy

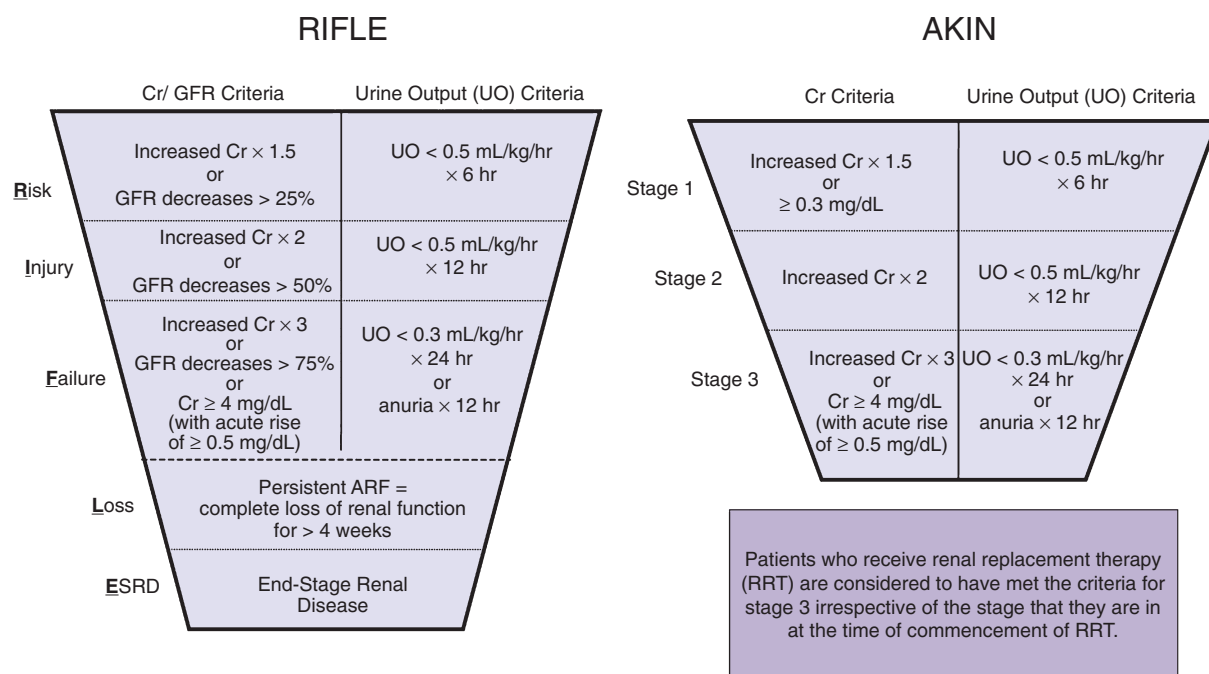

FIGURE 93-1 ■ The RIFLE and AKIN classifications for acute kidney injury. AKIN, Acute Kidney Injury Network; RIFLE, risk, injury, failure, loss of kidney function, and end-stage kidney disease. (From Critical Care 2009, 13:211. doi:10.1186/cc7759; and found on the website <http://www.ccforum.com/content/13/3/211>.)

the diagnostic criteria of HRS-1. The dominant clinical feature is severe ascites with poor or no response to diuretics. Patients with HRS-2 are especially predisposed to develop HRS-1 after precipitating events.⁴⁰⁻⁴² The median survival of patients with HRS-2 is 6 months, which is worse than patients with nonazotemic cirrhosis with ascites.

TREATMENT

Goals of therapy include improvement of liver function as in the recovery of alcoholic hepatitis, treatment of decompensated hepatitis B,⁴³ or medical therapy including pharmacotherapeutics and renal replacement therapy (RRT) as a bridge to either liver transplantation or simultaneous liver-kidney transplantation (SLK). To date, no single therapeutic agent has been found to permanently reverse HRS. Dopamine, fenoldopam, endothelin antagonists, natriuretic peptides, and angiotensin-converting enzyme inhibitors have been shown to either have no benefit or worsen the outcome of HRS.⁴⁴

Liver Transplantation

Liver transplantation is the treatment of choice for HRS.⁴⁵⁻⁴⁹ Immediately after transplantation, further impairment in GFR may be observed with the need for RRT.⁴⁵ Delay in the administration of nephrotoxic medications for 48 to 72 hours after transplantation may be considered.⁵⁰ GFR improves by 1 to 2 months postoperatively, but a moderate level of renal dysfunction persists and is more marked than in patients without HRS.³⁴ The hemodynamic and neurohormonal abnormalities associated with HRS usually resolve within the first month. However, not all patients exhibit renal recovery. Predictors of an HRS-1 reversal following liver transplantation are younger age, lack of chronic kidney disease (CKD), shorter durations of HRS and pretransplant dialysis, and lower preoperative creatinine.⁵¹ There is heterogeneity in the results of studies examining renal recovery post transplant, with results ranging from 58% to 100%.^{52,53}

Patients with HRS, who undergo transplantation have more complications, longer intensive care unit stay, and higher in-hospital

mortality rates.⁴⁵⁻⁴⁹ The 3-year probability of survival is 60%,⁴⁵⁻⁴⁹ which is only slightly less than that for liver transplant recipients without HRS.

SLK

SLK transplant is an option for patients at risk for nonrecovery. SLK should be used only for those who have irreversible kidney injury.^{54,55} At this time, however, renal recovery remains difficult to predict. The Organ Procurement and Transplantation Network (OPTN) liver and intestine committee and kidney committee proposed listing criteria for SLK candidate selection and allocation. Limitations include the definition of AKI, GFR determination, and timing of initiation and duration of dialysis.³⁹ Whereas some studies suggest that patients on RRT for more than 8 to 12 weeks have improved survival with SLK compared to liver transplant alone, there is significant variability.^{55,56,57} The consensus panel suggested liver transplantation alone in patients with HRS for less than 4 weeks.

Volume Expansion and Vasoconstrictors

Vasoconstrictors and volume expansion to increase splanchnic vasoconstriction and improve circulating volume may be the most promising medical approach for HRS. Over the past decade, many small studies have evaluated vasoconstrictors with and without a volume expander.

Volume administration, particularly with albumin, is an important tenet of therapy, with several studies showing that vasopressors alone are not as effective. It is important to avoid fluid overload. Assessment of intravascular volume is challenging, with physical exam findings or static measurements of filling pressures having poor accuracy in predicting a response to a fluid bolus.⁵⁸ The choice of fluid remains controversial,⁵⁹ although a consensus panel recommended albumin. The recommended albumin dose is 1 g of albumin/kg for 2 days, up to a maximum of 100 g/d followed by 20 to 40 g/d.³⁹ "Chloride liberal" fluid administration may be associated with AKI in critically

therapy increased the probability of reversal. Treatment with terlipressin and albumin may be associated with a survival benefit when including studies other than just placebo control studies.⁶⁴

The dose ranges used vary from 1 to 2 mg every 4 to 6 hours. Incremental increases in dosing while monitoring creatinine have been proposed.⁶⁷ A maximal dose of 12 mg/d with minimum duration of 3 to 5 days has been proposed.⁶² There are variable data on the rates of recurrence after discontinuation of therapy, ranging from 5.3% to 50%.^{69,44,62}

α -adrenergic agonists also have been used to augment renal perfusion. Duvoux⁷⁰ treated 12 patients with HRS-1 with intravenous (IV) albumin and norepinephrine. A significant improvement in serum creatinine was observed in 10 patients. Two RCTs compared norepinephrine to terlipressin.^{71,72} In the first study, reversal of HRS occurred in 70% of the patients in the norepinephrine group versus 83% in the terlipressin group. In the second study, norepinephrine was effective in increasing MAP, urine output, and decreasing creatinine. A recent meta-analysis found that norepinephrine is as effective as terlipressin when used in conjunction with albumin and that it appears to be associated with fewer adverse events.⁷³ Until recently, there has been scant evidence in the treatment of HRS-2. A recent RCT by Ghosh found that both terlipressin and norepinephrine are safe and effective with response rates of 74%.⁷⁴

Treatment with norepinephrine is limited to inpatient settings. Angeli⁷⁵ used oral midodrine, a α -adrenergic agonist, IV albumin, and subcutaneous octreotide in five patients with HRS-1. In all cases, there was a dramatic improvement in renal perfusion, GFR, serum blood urea nitrogen, creatinine, and sodium. Esrailian⁷⁶ retrospectively evaluated 60 patients, comparing midodrine plus octreotide to untreated controls. Patients in the treatment arm had an improvement in renal function and increased survival. In a prospective observational study with historical controls, Skagen et al.⁷⁷ studied midodrine and octreotide in patients with HRS-1 and HRS-2. Treatment was associated with an improvement in GFR and an increase in median survival. Studies of monotherapy of octreotide have not shown a benefit over placebo. The combination of midodrine plus octreotide is a promising regimen for HRS-2 as outpatients.

Recent research has focused on identifying predictors of treatment efficacy with vasoconstrictors. A change in MAP during treatment was the sole independent predictor of patient survival.⁷⁸ An increase in MAP of more than 10 mm Hg was associated with better overall survival with no further improvement despite higher targets. A treat to the target concept by the use of a specific MAP goal may potentially guide management.

In summary, these studies show the following:

1. HRS-1 can be reversible with IV albumin and vasoconstrictors.
2. Both components of the treatment are important.
3. Infusion of vasoconstrictors is associated with ischemic complications.
4. There is a delay between improvement in circulatory function and an increase in GFR.
5. Reversal of HRS improves survival, with a significant number surviving to transplantation.

Transjugular Intrahepatic Portosystemic Shunt

Decreasing portal pressure by portosystemic anastomosis to improve the circulatory compromise of cirrhosis has been targeted as a treatment for HRS. Case reports show that HRS can be reversed after a surgical portosystemic shunt.^{79,80}

Transjugular intrahepatic portosystemic shunt (TIPS) in the management of HRS-1 has been evaluated in small-scale studies and may

be of benefit in conjunction with vasopressors.⁸¹⁻⁸³ In one study of patients with HRS-1 who were not candidates for transplantation, it was found that the survival rates at 3, 6, and 12 months after TIPS were 54%, 50%, and 20%, respectively.⁸¹ TIPS may be beneficial in patients with HRS-2 with refractory ascites, with improvements in renal function without improved survival.⁸⁴ A more recent meta-analysis by Salerno, however, found TIPS significantly improved transplant-free survival of patients with cirrhosis and refractory ascites. Further research is needed to define the role of TIPS in the treatment of HRS.⁸⁵

Other Therapeutic Methods

Hemodialysis and arteriovenous or venovenous hemofiltration are a frequent bridge to liver transplantation or for treating an acute but reversible decompensation.⁸⁶ Continuous RRT is often selected in hemodynamically unstable patients, but there are no published studies that allow for evidence-based guidelines on one modality over the other.⁸⁷ Given that the prognosis of HRS-1 is poor without transplantation, strong consideration should be had for withholding RRT in patients who are not liver transplant candidates. These decisions should be made within the context of the patient's goals of care and involve shared decision making.

Noncell-based extracorporeal support systems are available that perform detoxifying functions of the liver. One such noncell-based support system uses an albumin-containing dialysate that is recirculated and perfused through charcoal and anion-exchanger columns. This modality has been shown to improve hemodynamics and reduce plasma renin in patients with HRS-1.^{88,89} In a small series of patients, improved survival was reported.⁹⁰ Modalities such as the Prometheus system and single-pass albumin dialysis have been used in a few patients with some success.^{91,92} However, further studies are needed in this area.

PREVENTION

Preventing precipitating factors, such as infections and acute alcoholic hepatitis, may decrease the incidence of HRS-1. Three randomized controlled studies enrolling a large series of patients have shown that HRS can be prevented in specific clinical settings. In the first study,⁹³ albumin together with cefotaxime was compared to cefotaxime alone in patients with SBP. Treatment with albumin markedly reduced the incidence of impaired circulatory function and the occurrence of HRS-1. The second study showed that oral prophylaxis using norfloxacin decreased the 1-year probability of developing SBP and HRS-1 and improved survival.⁹⁴ In a third study,⁹⁴ administration of the tumor necrosis factor synthesis inhibitor pentoxifylline to patients with severe acute alcoholic hepatitis reduced the occurrence of HRS (8% vs. 35%) and hospital mortality (24% vs. 46%).

CONCLUSION

The pathophysiology of HRS is characterized by intense vasoconstriction with splanchnic arterial vasodilation. HRS-1 is characterized by rapid and progressive deterioration of circulatory and renal function. It often develops following a precipitating event and carries a very poor prognosis (median survival rate <2 weeks). HRS-2 is characterized by steady deterioration of circulatory and renal function with refractory ascites. Patients with HRS-2 have a median survival of 6 months. The administration of albumin plus a vasoconstrictor is an effective treatment for HRS. These approaches may improve survival and may serve as a bridge to liver transplantation, which is the treatment of choice for these patients.

KEY POINTS

1. Portal hypertension leads to the production of vasodilators causing splanchnic vasodilation. This leads to activation of the renin-angiotensin-aldosterone system as well as the sympathetic nervous system, which causes renal vasoconstriction. Decreased renal perfusion due to an imbalance between extremely high vasoconstrictor tone and the decreased production of renal vasodilators leads to HRS.
2. Criteria of the International Ascites Club define HRS (see [Table 93-1](#)) as levels of creatinine above 1.5 mg/dL in the absence of other potential causes of renal failure.
3. HRS is classified into two types:
 - a. Type 1: severe and rapidly progressive renal failure, usually following a precipitating event, with a median survival of 2 weeks.
 - b. Type 2: moderate and steady development of renal failure, clinically characterized by refractory ascites, with a median survival of 6 months.
4. Liver transplantation is the treatment of choice for HRS. The recovery of renal function neurohumoral physiology may take 1 month.
5. The 3-year probability of survival in transplanted patients with HRS is 60%.
6. HRS-1 may be reversible after treatment with intravenous albumin and vasoconstrictors.
7. Successful prevention of HRS has been achieved in the setting of spontaneous bacterial peritonitis and acute alcoholic hepatitis.

DEFINITION

Hepatopulmonary syndrome (HPS) is defined by abnormal oxygen exchange in association with intrapulmonary vascular dilatation (IPVD) in patients with liver disease.¹ The presence of another cardiopulmonary disease that alters gas exchange does not exclude this diagnosis.²⁻⁵ HPS is most commonly associated with cirrhosis¹ and portal hypertension, but neither of these is required.⁶ The correlation between the degree of liver dysfunction and the presence^{7,8} and severity^{3,4,7,9,10} of this syndrome is debated.

CLINICAL FEATURES

HPS usually presents as dyspnea^{6,11} in patients who are already known to have liver disease. HPS-induced shortness of breath often is relieved when the patient is lying down (platypnea).^{11,12} There are no consistently noted physical examination findings.^{6,13} Hypoxia is often worse in the standing position (orthodeoxia),¹² and it generally can be corrected with sufficient supplemental oxygen.^{1,3,4,10,14}

PATHOPHYSIOLOGY

Dilated precapillary vessels and pleural-based arteriovenous (AV) connections are noted at autopsy in cases of HPS.¹⁵ Current thinking suggests that these abnormal vessels develop due to an excess of pulmonary vasodilators,¹ which cause hypoxia through ventilation/perfusion (V/Q) mismatching, AV shunting, and the limitation of oxygen diffusion to red blood cells (RBCs) in the center of the vessel.¹⁵⁻¹⁷ The hyperdynamic circulation, which is characteristic of cirrhosis, exacerbates this problem by decreasing RBC transit time through the pulmonary capillaries, further limiting oxygen diffusion.^{15,17} Orthodeoxia is due to a worsening of V/Q mismatch and AV shunting in the standing position.¹⁸

Nitric oxide (NO) has been implicated as a key vasodilator in HPS. Exhaled NO levels are elevated in patients with cirrhosis compared to healthy controls and in HPS patients compared to cirrhotic patients without HPS. NO levels correlate with the severity of cirrhosis and gas exchange abnormalities.¹⁹ In rat models of HPS induced by common bile duct ligation (CBDL), increased levels of endothelial²⁰ and inducible NO synthase (eNOS and iNOS) have been observed, and the administration of a NO synthase inhibitor prevents the development of pulmonary vasodilation and HPS.²¹

Excess eNOS, located in the pulmonary arteries and capillaries, is associated with impaired vasoconstriction. Levels of this enzyme correlate with the degree of gas exchange abnormalities.²⁰ CBDL rats demonstrate increased hepatic production of endothelin-1 (ET-1)²² and increased vascular expression of the endothelin-B receptor (ET-B)²³ in proportion to the severity of gas exchange abnormalities.^{22,24} Interaction between the ET-1 and the ET-B receptor is believed to be the trigger for increased eNOS expression. This theory is supported by data that show a reduction in eNOS expression and an improvement in HPS when CBDL animals are treated with ET-B receptor antagonists.²⁴

iNOS is expressed in macrophages found in the lungs of CBDL rats,²¹ while treatment with norfloxacin is associated with a reduction in the rate of gram-negative bacterial translocation, accumulation of pulmonary macrophages, production of iNOS, and severity of HPS.²⁵

Pulmonary macrophages in CBDL rats also express elevated levels of heme-oxygenase-1 (HO-1), an enzyme that catalyzes the formation of the vasodilating gas and carbon monoxide (CO).²⁶ Increased levels of carboxyhemoglobin (COHb) have been observed in rat²⁶ and human²⁷ subjects with HPS, and treatment with an HO-1 inhibitor normalizes COHb levels and partially alleviates HPS in CBDL rats.²⁶ These data suggest that CO also contributes to pulmonary vasodilation in HPS.

Tumor necrosis factor alpha (TNF- α) rises in CBDL rats in association with ET-1 and endotoxin levels, and it has been proposed to influence the accumulation of the iNOS and HO-1-producing pulmonary macrophages.²⁸ Administration of pentoxifylline, a phosphodiesterase inhibitor that suppresses the production of TNF- α , is associated with a reduction in pulmonary macrophage accumulation, ET-B receptor and eNOS expression, and the severity of HPS.²⁹

More recently, ET-1 and ET-B receptor activation have been shown to increase pulmonary intravascular monocyte adherence through the monocyte chemokine, fractalkine.^{30,31} Fractalkine promotes angiogenesis directly and through monocyte secretion of vascular endothelial growth factor-A.³¹ Angiogenesis is emerging as an important feature in experimental models of HPS and may provide new therapeutic targets, as well as explain the delay in the resolution of hypoxia in patients post-transplantation.

DIAGNOSIS

HPS should be considered in any patient with liver disease and dyspnea or hypoxia. Evaluation begins with arterial blood gas (ABG), with the patient seated, resting, and breathing room air.^{6,17} Further evaluation is recommended when the PaO₂ is less than 80 mm Hg or the alveolar-arterial oxygen gradient (A-a gradient) is 15 mm Hg or greater (≥ 20 mm Hg for patients over age 64 years).¹⁷

HPS diagnosis requires the presence of ABG changes that cannot be fully explained by comorbid cardiopulmonary disease. Conditions frequently coexisting with cirrhosis that may influence gas exchange include chronic obstructive pulmonary disease, congestive heart failure, restrictive lung disease due to ascites or hepatic hydrothorax, α_1 -antitrypsin deficiency, and portopulmonary hypertension (distinguished from HPS by its increased pulmonary artery pressure and vascular resistance).³² Patients should have a chest x-ray (CXR) and pulmonary function tests¹² to assess for pulmonary disease. Of note, increased markings at the lung base on CXR^{1,6,8} and the reduced diffusion capacity for CO (DLCO)^{3,4,7,13,18} are common findings in HPS and in isolation, do not exclude the diagnosis. An echocardiogram evaluates cardiac function, often concurrently with IPVD assessment (see later discussion).

When a gas exchange abnormality is present and not fully explained by another cardiopulmonary disease, the patient should be evaluated for the presence of IPVDs. Contrast-enhanced echocardiography (CEE) is commonly used for this purpose as it is widely available and it permits concurrent evaluation for cardiac causes of abnormal gas exchange.¹² Agitated saline is used as a contrast media which creates a stream of microbubbles after injection. In healthy subjects, these microbubbles opacify the right heart only as they are filtered through the pulmonary capillary bed due to their size (greater than 15 μ m in diameter).^{9,33} Intracardiac shunts can be distinguished from

FIGURE 94-1 ■ Photos of contrast-enhanced echocardiography. Top left: Agitated saline enters the right ventricle. Top right: Saline enters the left atrium posteriorly. Bottom left: Saline density is equal in the right and left ventricles. Bottom right: Saline density in the left ventricle exceeds the right ventricle after multiple cardiac cycles. (Photos courtesy of Karl Q. Schwarz, MD. University of Rochester Medical Center, Rochester, NY.)

intrapulmonary shunts based on the number of cardiac cycles required for agitated saline to pass from the right to the left atrium in the apical four-chamber view (Fig. 94-1). In general, contrast appears in the left atrium within three cycles in intracardiac shunts while it takes 4-6 cycles in intrapulmonary shunts.^{9,33} CEE is highly sensitive for evaluation of IPVDs³⁴ and may document them in up to 82% of patients tested.³³ Patients with a positive CEE have a greater incidence of dyspnea³⁵ and abnormal CXRs,^{9,35} as well as more severe cirrhosis^{9,33,35} and gas exchange abnormalities.^{9,35} However, many patients with IPVDs demonstrated by CEE do not have gas exchange abnormalities,^{5,8,13,33,35} and so this test is not specific for HPS.³⁴

Technetium-99m-labeled macroaggregated albumin (MAA) perfusion lung scanning is an alternative test for IPVDs. It is expensive, requires radiation exposure,¹³ and cannot document the site of shunting. However, it can provide a quantitative shunt fraction^{13,17,34} that correlates directly with the A-a gradient^{3,10,14} and inversely with the room air PaO₂ and oxygen saturation.^{3,10,14,36} Perfusion scanning is less sensitive than CEE for IPVD detection but more specific.^{5,10,36} These test characteristics have enabled CEE to be advocated as the first line for evaluating patients with liver disease and abnormal gas exchange.^{5,10,17} If CEE is positive but the relative contributions of other cardiopulmonary disease and HPS are not clear, perfusion lung scanning can determine if HPS is present.^{5,10,12,17}

PREVALENCE

The reported prevalence of HPS varies greatly depending on which diagnostic criteria are used. Using currently recommended criteria, (elevated A-a gradient and positive CEE) 8%-33% of patients being evaluated for liver transplant have HPS.^{8,9,37}

PROGNOSIS

In the absence of liver transplantation, patients with HPS have a poorer functional status, reduced self-reported quality of life,⁸ and a worse survival^{7,8,38} than non-HPS controls matched for severity of liver disease. HPS patients who die during follow-up have been noted to have greater room air PaO₂ reductions, A-a gradient elevations, and shunt fractions than those who survive,^{3,7,38} but this is not a universal finding.⁸ Without a transplant, HPS patients demonstrate progressive hypoxemia.³⁸ Despite this, death is usually due to complications of liver disease^{7,17,38} rather than primary respiratory failure.³⁸

THERAPY

Liver transplantation is the only definitive therapy for HPS and should be considered when patients are symptomatic or have a

$\text{PaO}_2 \leq 60$ mm Hg.^{6,17} Multiple therapies have been tried for HPS without clear efficacy, including inhibitors of NO,³⁹⁻⁴¹ antibiotics,⁴² pentoxifylline,^{29,43,44} mycophenolate mofetil,⁴⁵ transjugular intrahepatic portosystemic shunt,^{12,46} and pulmonary angiography with embolization of dilated capillaries⁴⁷ or AV communications.⁴⁸ Oxygen therapy also has been recommended, although clinical benefit has not been confirmed.^{1,6,11,12,17,37}

Owing to the increased mortality associated with HPS and the lack of other effective therapies, the United Network for Organ Sharing (UNOS) has adjusted organ allocation algorithms to prioritize patients with HPS and a $\text{PaO}_2 \leq 60$ mm Hg.^{49,50} Compared to earlier case series

showing increased posttransplant mortality in HPS,¹⁴ patients who receive these model for end-stage liver disease (MELD) exception points have better pretransplant survival than those without HPS and similar posttransplant outcomes.^{49,50} Also in contrast to prior reports, the largest single-center HPS transplant study found no difference in posttransplant outcomes in patients with very severe hypoxia ($\text{PaO}_2 < 50$ mm Hg),⁵⁰ while an analysis of the UNOS database demonstrated increased mortality in patients with a $\text{PaO}_2 \leq 44$ mm Hg.⁴⁹ Among those patients who survive the perioperative period, improvement in or resolution of HPS is noted in the majority of cases, although the amelioration of symptoms may require a year or more to occur.^{4,14,38}

KEY POINTS

1. Hepatopulmonary syndrome (HPS) consists of a triad of liver disease, abnormal pulmonary gas exchange, and intrapulmonary vascular dilatation. It most commonly presents as dyspnea or hypoxia in patients already known to have liver disease.
2. HPS is believed to result from excessive pulmonary vasodilation. Pulmonary vasodilatation leads to hypoxia through ventilation/perfusion mismatching, arteriovenous shunting, and limitations to oxygen diffusion.
3. Diagnosis of HPS requires a seated, room air, arterial blood gas to document abnormal gas exchange, as well as confirmation of an intrapulmonary shunt using echo or lung perfusion scanning. Prevalence of HPS is thought to be 8%-33% in patients undergoing evaluation for liver transplantation.
4. Patients with liver disease and HPS have an increased risk of death relative to patients with liver disease alone. Liver transplantation is the only effective therapy and improves or resolves HPS in most cases. Transplant evaluation should be pursued in patients with HPS who are symptomatic or have a seated room air PaO_2 less than 60 mm Hg.

Hepatic encephalopathy encompasses a spectrum of neuropsychiatric abnormalities that occur in patients with liver disease in the absence of other brain disease.^{1,2} The spectrum includes personality changes, impaired mental function, motor abnormalities (i.e., asterixis, tremors, hyperventilation, hyperactive reflexes), and altered consciousness. A consensus panel of experts has proposed the classification of hepatic encephalopathy into *type A*, associated with acute liver failure; *type B*, associated with portosystemic bypass without intrinsic liver disease; and *type C*, associated with chronic liver disease.³

The encephalopathy accompanying acute liver failure (*type A*) is commonly associated with cerebral edema and increased intracranial pressure (ICP), exhibits an abrupt onset with a short prodrome and rapid progression, and often ends with the death of the patient.^{4,5} Patients sequentially experience drowsiness, delirium, agitation or convulsions, decerebrate rigidity, unresponsiveness, and deep coma within a comparatively short period of time, usually hours to days. Irreversible neurologic damage may occur as a result of brain ischemia or herniation. Patients who develop coma in the setting of acute liver failure have a grave prognosis; fewer than 20% survive without hepatic transplantation.⁶

In patients with chronic liver disease, encephalopathy (*type C*) develops insidiously and is often heralded by a change in mental or behavioral status. Encephalopathy may be episodic, persistent, or minimal and subclinical.³ Episodes are sporadic, characterized by exacerbations and remissions, and are generally precipitated by inciting events.¹⁻² Although the initial manifestation of portosystemic encephalopathy (PSE) is usually a subtle change in mentation, neurologic dysfunction may progress and be classified according to confusion, lethargy, and even coma (Table 95-1). Neurologic signs vary and fluctuate but usually include asterixis, hyperreflexia, clonus, and an extensor plantar response. Causes of PSE may not always be apparent but should always be investigated (Box 95-1). In some patients, minimal encephalopathy may not be clinically obvious but only detectable by psychometric testing. By these tests, about two-thirds of cirrhotic patients with portal hypertension have unsuspected minimal hepatic encephalopathy.⁷⁻⁹ Patients who undergo portosystemic shunt or bypass procedures, either surgical or transjugular intrahepatic portosystemic shunt (TIPS), often develop encephalopathy (*type B*) which is similar to the encephalopathy experienced by patients with chronic liver disease.

■ GENERAL PRINCIPLES

No single abnormality of hepatic or neurologic metabolism adequately explains all of the clinical, biochemical, physiologic, or experimental findings of encephalopathy occurring in patients or animal models.^{1-2,5} Abnormalities of multiple neurotransmitters including glutamate, γ -aminobutyric acid (GABA), dopamine, serotonin, and opioids have been described, as well as increased plasma levels of a wide array of potential neurotoxins (ammonia [NH_3], GABA, short-chain fatty acids, and methanethiols).^{10,11} Regardless of the mechanism(s) of hepatic encephalopathy, marked changes in central nervous system (CNS) glial cells are noted on neuropathologic examination in patients with hepatic encephalopathy. Encephalopathy associated with acute liver failure is typically characterized by astrocytic swelling, whereas

encephalopathy from chronic liver disease is characterized by Alzheimer type II astrocytosis.¹¹

Cerebral Blood Flow

In acute liver failure, the brain is potentially subject to hypoxic injury due to complications such as systemic arterial hypotension, respiratory failure, and a reduction in cerebral blood flow that accompanies cerebral edema and intracranial hypertension. Therapy is often directed at optimal oxygenation, maintenance of cerebral perfusion pressure (goal >40 mm Hg), and reduction of ICP (goal <20 mm Hg).^{4,7} Clinical data suggest that cerebral blood flow is relatively low initially but subsequently increases with increasing blood concentrations of NH_3 .¹²⁻¹⁵ Paradoxically, increases in cerebral blood flow may aggravate cerebral edema and worsen neurologic damage.

Cerebral Glucose and Oxygen Metabolism

Brain energy metabolism is unique in that glucose is the only substrate under normal physiologic conditions, and its uptake and utilization by the brain are independent of insulin.¹⁶⁻²⁰ Ammonia accumulation during hepatic failure in humans or in experimental models of hyperammonemia is associated with altered cerebral glucose metabolism. In early acute liver failure, prior to the onset of intracranial hypertension, cerebral glucose metabolism and oxygen consumption are proportionately diminished.¹⁶ There is no evidence of cerebral hypoxia, implying that reduced glucose and oxygen utilization reflects a diminished metabolic demand by the brain at this early stage. Thus, prior to the development of intracranial hypertension, cerebral glucose and oxygen metabolism are reduced, but these changes are consistent with normal aerobic metabolism and physiologic regulation. After the development of intracranial hypertension, oxygen metabolism remains reduced but measurements of cerebral glucose utilization vary from reduced rates to increased rates, and glycolysis may be accelerated.^{17,18,20} These findings suggest that the progression of acute liver failure and development of intracranial hypertension are associated with relative cerebral hypoxia and a switch to anaerobic metabolism.

Ammonia Hypothesis

The *ammonia hypothesis* states that the major mechanism of hepatic encephalopathy is excessive accumulation of NH_3 , which induces neuronal metabolic derangements and also promotes astrocytic swelling.²¹ In addition, NH_3 perturbs cerebral nitric oxide metabolism, which can mediate some of these effects.²² Blood NH_3 originates mainly from four sources: intrahepatic deamination of amino acids, extrahepatic metabolism of nucleotides, gut metabolism of glutamine, and bacterial degradation of intestinal protein and urea.²³ More than 50% of blood NH_3 is derived from the latter source.

NH_3 is normally metabolized by the liver to either urea or glutamine by the actions of carbamoyl-phosphate synthetase I and glutamine synthetase, respectively. Patients with hepatic failure have impaired NH_3 metabolism related to a reduction in liver metabolism and an increase in portosystemic shunting. As a result, an elevation in blood NH_3 concentration is a characteristic feature of severely impaired hepatic function. Certain clinical and experimental

TABLE 95-1

Stages of Encephalopathy in Chronic Liver Disease (West Haven Criteria)

| STAGE | CLINICAL SIGNS |
|-----------|---|
| Stage I | Mental slowness, euphoria or anxiety, shortened attention span, impaired calculating ability |
| Stage II | Lethargy or apathy, inappropriate behavior, personality change, more obvious problems with calculations |
| Stage III | Lethargic, somnolent, marked confusion and disorientation, but responds to verbal stimuli |
| Stage IV | Coma, patient may or may not respond to noxious stimuli |

Patients with chronic liver disease rarely, if ever, demonstrate cerebral edema, regardless of the stage of encephalopathy.

BOX 95-1

Clinical Events Precipitating Hepatic Encephalopathy in Patients with Cirrhosis

Gastrointestinal hemorrhage
 Infection (including spontaneous bacterial peritonitis)
 Sepsis
 Dehydration
 Imbalance of electrolytes or acid-base
 Renal failure
 Drugs, toxins, medications (especially sedative-hypnotics or narcotics)
 Illicit substances
 Alcohol
 Dietary indiscretion (excessive protein intake)

observations link the increase in blood, particularly arterial, NH_3 concentration to hepatic encephalopathy.^{10,11,24,25} Hyperammonemia and elevated concentrations of NH_3 within the cerebrospinal fluid (CSF) are features of acute and chronic hepatic encephalopathy, Reye syndrome, deficiencies of urea cycle enzymes, and sodium valproate toxicity. In patients with cirrhosis or portosystemic shunts, ingestion of NH_3 -generating substances (proteins, amino acids, urea, ammonium salts) may precipitate encephalopathy. In animal models, chronic administration of ammonium salts results in Alzheimer type II astrocytosis, a change indistinguishable from that observed in patients with chronic hepatic encephalopathy.¹¹

Further support for the ammonia hypothesis originates from the clinical benefits of several medications. Production of NH_3 from the intestine is reduced by orally administered nonabsorbable antibiotics such as rifaximin and neomycin, as well as nonabsorbable disaccharides including lactulose, lactitol, and lactose (in lactase-deficient patients). These treatments lower plasma NH_3 concentration and improve subjective and objective measures of encephalopathy.

Other clinical and experimental observations refute the link between NH_3 and hepatic encephalopathy. Blood levels of NH_3 are elevated in patients with cirrhosis regardless of the presence or absence of encephalopathy. Furthermore, some patients with hepatic encephalopathy have normal blood levels of NH_3 . The grade of hepatic encephalopathy does not correlate with the blood concentration of NH_3 . Seizures and hyperexcitability are commonly observed in animal models of NH_3 intoxication and in human congenital hyperammonemia but are rarely observed in patients with chronic hepatic encephalopathy.

Other Potential Hypotheses for Hepatic Encephalopathy

The glutamine-glutamatergic neurotransmitter system has been implicated in the pathogenesis of hepatic encephalopathy because the

FIGURE 95-1 ■ (A) Glutamine forms predominantly in the astrocyte, is pumped out, and taken up by presynaptic neurons where it is converted to glutamate. Nerve stimulation releases glutamate from the presynaptic neuron to serve as an excitatory neurotransmitter. Astrocytes avidly take up glutamate from the synaptic cleft to abolish neuronal stimulation. (B) Ammonia freely diffuses across the blood-brain barrier and stimulates formation of glutamine by the astrocyte via the action of glutamine synthetase (1). Ammonia also blocks the export of glutamine from the astrocyte at the synaptic cleft (2). The net effect of these two actions is increased concentration of glutamine within astrocytes, which promotes astrocyte swelling.

glutamatergic excitatory neurotransmitter system in the CNS is markedly altered in patients with both acute and chronic liver disease and in animal models of hepatic encephalopathy.^{6,21,22} CNS astrocytes are a major regulatory cell in the glutamatergic system and are responsible for the termination of glutamate-induced excitation.¹¹ When glutamate is taken up by the astrocyte, it is metabolized to glutamine via the action of glutamine synthetase, which utilizes blood-derived NH_3 (Fig. 95-1). The hyperammonemia of liver failure favors the formation of glutamine but also impairs the release of glutamine from the astrocyte. The accumulation of osmotically active glutamine in the astrocyte is associated with cell swelling and can lead to accumulation of glutamate in the extracellular fluid. Clinically, levels of glutamine and glutamate increase in CSF fluid during hyperammonemic states, and CSF concentrations of glutamine correlate loosely with the stage of encephalopathy.

The γ -aminobutyric acid (GABA)-benzodiazepine receptor hypothesis is another important mechanism that likely plays a role in hepatic encephalopathy. GABA is an inhibitory neurotransmitter found throughout the CNS.²⁶ The *GABA hypothesis* states that an excess of

GABA or increased sensitivity of GABA receptors to neurosteroids is responsible for hepatic encephalopathy.^{26,27} GABA originates from the intestine, and plasma levels increase in hepatic failure due to inadequate hepatic extraction. During acute liver failure, the blood-brain barrier (BBB) becomes more permeable and increased amounts of GABA enter the CNS. Once in the brain, GABA binds to its receptor to produce neuroinhibition and clinical encephalopathy. A key component to understanding the relationship of GABA and benzodiazepines was the recognition that the GABA receptor was tightly linked to and modulated by the benzodiazepine receptor.²⁷⁻³¹ The *GABA hypothesis* predicts that benzodiazepines would increase the severity of hepatic encephalopathy and that benzodiazepine antagonists such as flumazenil might ameliorate hepatic encephalopathy. Clinical experience suggests that cirrhotic patients, especially those with encephalopathy, are particularly sensitive to the amnesic and sedative effects of benzodiazepines. In our experience, use of benzodiazepines and other sedative/hypnotics is a common cause of exacerbations of hepatic encephalopathy. Recent studies have demonstrated that patients with hepatic encephalopathy have increased plasma levels of benzodiazepines or “natural” benzodiazepine-like compounds that may act as “false neurotransmitters.”^{32,33}

Previously Studied Agents Associated With Hepatic Encephalopathy

Numerous clinical studies have found alterations in levels of other agents or pathways in patients with hepatic encephalopathy. These agents or pathways include the dopaminergic and serotonergic systems, taurine, methanethiols, short-chain fatty acids, manganese, and zinc. However, conclusive evidence to support or refute their association with hepatic encephalopathy is lacking, and clinical and bench research of these agents as causative or therapeutic targets has been abandoned for over a decade.

ENCEPHALOPATHY IN THE SETTING OF ACUTE LIVER FAILURE

Definition

Acute liver failure, also referred to as *fulminant hepatic failure*, is defined by the development of coagulopathy (prothrombin time [PT] >20 seconds prolonged with an international normalized ratio [INR] >1.5) and hepatic encephalopathy in a patient with acute hepatitis who lacks underlying chronic liver disease (except in Wilson's disease).³⁴⁻³⁷ Patients with acute liver failure usually have extreme elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) with the initial injury (e.g., 1000 to 5000 IU/L), are often jaundiced, and exhibit constitutional symptoms. They are at risk of encephalopathy, although most recover uneventfully. Progressive hepatic encephalopathy is a poor prognostic sign and signals the need for hepatic transplantation.

Prognosis

A major determinant of prognosis is the level of encephalopathy (see Table 95-1). Patients with acute liver failure who have progressed to higher stages of encephalopathy (i.e., stage III or IV) have the worst prognosis. The King's College Criteria or Glasgow Coma Scale are useful in assessing the need for transplantation.^{36,38} Cerebral edema on computed tomography (CT) scan of the brain is a late feature of progressive encephalopathy (Fig. 95-2). Additional clinical features that indicate a poor prognosis include metabolic acidosis, renal failure, severe jaundice, or markedly prolonged prothrombin time.³⁸⁻⁴¹

General Clinical Management

Once recognized, patients with acute liver injury and encephalopathy should be transferred to a center with expertise in managing acute liver

FIGURE 95-2 ■ Magnetic resonance image (MRI) of a T₁-weighted sagittal view of the brain demonstrating hyperintensity of the globus pallidus (whitish area indicated by arrow) that may be related to manganese deposition.

failure so that liver transplantation can be offered if indicated. Further recommendations on intensive care management of the patient with acute liver failure is beyond the scope of this chapter but is addressed elsewhere (see Chapter 96).

USE OF INTRACRANIAL PRESSURE MONITORING

Advantages

The use of intracranial pressure (ICP) monitoring in the management of high-grade encephalopathy (i.e., stage III or IV) in acute liver failure remains controversial. Several studies advocate ICP monitoring for its ability to provide important prognostic information about neurologic recovery after hepatic transplantation and in managing intracranial hypertension (ICH) while awaiting liver transplantation.⁴² Therefore, ICP monitoring could be considered for patients with high-grade encephalopathy who are on the transplant wait list. Also, centers could consider ICP monitoring in nontransplant candidates if there is a reasonable likelihood of spontaneous recovery, such as in acetaminophen-induced acute liver failure. In addition to helping with the management of ICH, ICP monitoring assists with close monitoring during the crucial perioperative period of liver transplantation, since it has been found that there is a transient increase in ICP that can last for about 12 hours postoperatively after dissection of the native liver and reperfusion of the graft.³⁷

Disadvantages

However, the use of ICP monitoring may lead to severe complications such as intracranial hemorrhage in these already critically ill patients with coagulopathy. In addition, several nonrandomized studies have failed to demonstrate an improvement in survival with the use of ICP monitoring.⁴² One prospective study of 92 patients with acute liver failure, high-grade encephalopathy, and ICP monitoring found a 10.3% rate of intracranial hemorrhage that likely contributed to the death of two patients.⁴² However, nearly half of the cases of intracranial bleeding were incidental radiographic findings without clinical consequence. Regardless of ICP monitor usage, 30-day survival post transplant was approximately 85%. Other reports confirm that bleeding complications

from the placement of ICP monitoring devices in patients with acute liver failure are mostly mild and without clinical significance.^{42,43} One study demonstrated the effectiveness of recombinant factor VIIa in preventing intracranial bleeding in 11 patients with acute liver failure who required ICP monitoring.⁴⁴ Overall, use of ICP monitoring remains controversial, but experts agree that these devices should not be used in patients with mild hepatic encephalopathy (i.e., stage I or II) or in patients with evidence of cerebral herniation, hypotension, or imminent death.

MANAGEMENT OF ENCEPHALOPATHY AND INTRACRANIAL HYPERTENSION

Encephalopathy is a hallmark of acute liver failure. The encephalopathy of acute hepatic failure is related to both metabolic factors, such as progressive elevation in blood NH_3 concentration, and cerebral edema. Progressively worsening encephalopathy is an ominous clinical feature in acute liver failure; development of grade III or IV encephalopathy may herald the death of the patient due to cerebral edema, increased ICP, and central herniation of the brain. Efforts to control the encephalopathy of acute liver failure are directed at preventing or resolving cerebral edema (Box 95-2).^{42,45-48} Because emerging evidence suggests that NH_3 may play a role in the development of cerebral edema, we recommend that administration of protein should be limited to less than 40 g/day in adults, and lactulose (20-40 g/day in divided doses) should be administered enterally to purge the bowel. However, one

must exercise caution when using lactulose in the setting of acute liver failure; dosing should be monitored carefully and adjusted to avoid excessive diarrhea, alterations in electrolytes, and volume depletion. If oral (PO) lactulose is given simultaneously with intravenous (IV) mannitol, marked deficits of free water can develop, inducing severe hyponatremia. Although one recent study suggested that infusion of hypertonic (3%) saline to maintain serum sodium concentration between 145 and 155 mEq/L is beneficial,⁴⁹ rapid shifts in sodium concentration have been associated with central pontine myelinolysis. Further discussion of hypertonic saline is provided later in this chapter. Administration of terlipressin or vasopressin may worsen intracranial hypertension and should be avoided.⁵⁰

Reversal of coagulopathy prior to placement of ICP transducers is recommended but exact targets (INR < 1.5 to 1.9) vary from center to center. Caution should be used as reversal of coagulopathy may be difficult and require large volumes of fresh frozen plasma (FFP), potentially contributing to volume overload and worsening of cerebral edema. Recombinant human factor VIIa infusion (40 $\mu\text{g/kg}$ bolus, repeated as needed every 4 hours to correct INR) may be preferred over FFP in this setting for limiting volume infusion and rapidly correcting the PT/INR.

Hepatic glycogen, the main storage supply of glucose, is depleted early in the course of acute liver failure predisposing to severe, potentially life-threatening hypoglycemia and worsening of cerebral energy metabolism. All patients with acute liver failure should be treated with glucose infusions, and blood glucose concentration must be monitored frequently.

Second-Line Therapies for Treatment of Mannitol-Refractory Intracranial Hypertension

Hypothermia in Acute Liver Failure

Therapeutic hypothermia or intentional reduction of core body temperatures has been increasingly used to treat hypoxic brain injury after cardiac arrest. Animal models of acute liver failure suggest that hypothermia may be effective in the prevention of cerebral edema.^{51,52} Several case series suggest that therapeutic hypothermia may have some efficacy in patients awaiting liver transplantation.^{19,53-55} However, a multicenter retrospective cohort study from the U.S. Acute Liver Failure Study Group revealed that hypothermia (body temperature target 32°C to 35°C) improved 21-day overall and transplant-free survival in only a subset of young (<25 years) patients with acetaminophen (APAP)-associated acute liver failure and high-grade encephalopathy, but not for the entire cohort of 97 patients.⁵⁶ Based on this analysis, physicians must wait for a prospective trial to further elucidate the use of hypothermia in this clinical setting.

Hypertonic Saline in Acute Liver Failure

Another possible method for treating refractory ICH during acute liver failure is the use of hypertonic saline. There has been great concern about the use of hypertonic saline because of the potential consequence of osmotic shifts across the BBB. However, a presumed advantage of hypertonic saline for the treatment of ICH is a higher osmotic reflection coefficient across the BBB.⁵⁷⁻⁵⁹ Thus, hypertonic saline could potentially lead to reduction in cerebral edema, lower ICPs, and improved perfusion by developing a higher osmotic gradient in the cerebral vascular compartment. In a randomized placebo-controlled study, Murphy et al. studied the effect of hypertonic saline infusion on the induction of hyponatremia in patients with ICP, and clinical outcomes among ICU patients with acute liver failure.⁶⁰ Fifteen patients were treated with 30% hypertonic saline (5-20 mL/hour) to maintain serum sodium levels between 145 and 155 mmol/L. After 24 to 72 hours, ICP reduction was significantly greater in the treatment group compared to the standard care group. However, high osmolar loads and continuous hemofiltration were required, and mortality was similar between both treatment and standard care groups. The use of hypertonic saline in the management of ICH in acute liver failure warrants further investigation, but its use is accepted as prophylactic

BOX 95-2

Measures Used to Monitor and Control Cerebral Edema Due to Acute Liver Failure

- Correction of metabolic abnormalities.
 - Electrolytes (Na, K, Cl, HCO_3).
 - Acid-base (if patient is on mechanical ventilation, induce mild respiratory alkalosis).
 - Glucose (maintenance intravenous glucose infusion).
- Avoid overtransfusion or overhydration.
 - Carefully match intake and output once patient is euvolemic.
 - Daily weight.
 - Avoid use of blood products unless indicated for ongoing bleeding and correction of coagulopathy or to maintain hemostasis when intracranial monitor has been placed. In the latter circumstance, the patient may require diuresis to avoid an excess in intravascular volume, especially from plasma.
- Institute dialysis in patients in renal failure.
 - Continuous arteriovenous or venovenous hemodialysis is preferred over standard hemodialysis.
 - Avoid severe volume shifts, stabilize blood pressure, maintain euvolemia, correct electrolyte and acid-base abnormalities.
- Mechanical ventilation (worsening encephalopathy, >grade II).
 - Main indication in liver failure is airway protection to prevent aspiration pneumonia.
 - Induce mild respiratory alkalosis (pH 7.45-7.50, Pco_2 20-30 mm Hg).
 - Elevate head of bed 15-30 degrees.
 - Use sedation to avoid having the patient "fight the endotracheal (ET) tube."
- Consider placement of intracranial pressure (ICP) monitor in the epidural space.
 - Should be considered when patients evolve from stage II (agitated confusion) to stage III (stuporous) encephalopathy.
 - Maintain adequate platelet count (>60,000) with platelet transfusions and INR < 1.5 with fresh frozen plasma if necessary.
 - Mannitol is used to control ICP in patients with intact renal function or in those on dialysis. Mannitol is given in 0.5-1 g/kg doses. Serum electrolytes, glucose, and osmolality should be checked every 4-6 hours. If ICP is elevated, osmolality < 310, and Na < 145, then give mannitol. Mannitol should be withheld if the patient has excessive serum osmolality or significant hyponatremia.

therapy by societal guidelines for patients with the highest risk of developing cerebral edema.⁶¹

Other Options for Refractory ICH

Other potential therapies that can be considered in acute liver failure patients with refractory ICH include barbiturates such as pentobarbital or thiopental and indomethacin. By inducing a comatose state and reducing cerebral edema, pentobarbital (3–5 mg/kg IV load, then 1–3 mg/kg/hour infusion) or thiopental (5–10 mg/kg load, then 3–5 mg/kg/hour infusion) have been shown to have some benefit in refractory ICH.^{62,63} However, severe side effects such as arterial hypotension, hypokalemia, and prolonged coma limit their use and often necessitate the coadministration of vasopressors in order to maintain cerebral perfusion pressure above 50 mm Hg. Indomethacin (dosed at 25 mg IV over 1 minute) also has the potential to cause an acute decrease in ICP and an acute increase in cerebral perfusion pressure (CPP) by causing cerebral vasoconstriction but has not been validated in a trial. Therefore, these medications may play a role as second- or third-line options for patients with persistent refractory ICH.^{64–66}

Experimental Therapies

Several other methods have been tested in acute liver failure: exchange blood transfusion, plasmapheresis, cross-circulation with human and baboon donors, hemoperfusion through isolated human or animal livers, hemodialysis (conventional and polyacrylonitrile), and column hemoperfusion (microencapsulated charcoal, albumin-covered Amberlite XAD-7 resin). Since none of these techniques has been demonstrated to improve survival, their use in the management of acute liver failure is not currently recommended.

Promising strategies that have been investigated in the management of patients with high-grade encephalopathy in the setting of acute liver failure include an extracorporeal liver assist device based on albumin dialysis (MARS). However, its use did not yield clear survival benefit.⁶⁷ Bioartificial liver (BAL) machines have also emerged as a potential therapeutic intervention. To date, there has only been one large randomized multicenter trial of the use of BAL in acute liver failure, and it did not conclude a survival benefit.⁶⁸ Finally, the use of human hepatocyte transplantation in the setting of acute liver failure as a bridge to transplantation is in persistent development.^{69,70}

Liver Transplantation

Liver transplantation is the only treatment that has been proven to improve survival in patients with acute liver failure and high-grade encephalopathy.^{6,71} Survival without transplantation is 10% to 20%. Survival increases to 60% to 80% with liver transplantation. In the largest series of living donor liver transplants for acute liver failure, Lee et al. report patient survival as 82.3% at 5 years after transplantation.⁷² These results are similar to those of cadaveric transplantation for acute liver failure and also demonstrate the durability of living donor allografts.

At some stage cerebral edema becomes irreversible and patients, despite transplantation, will experience brain death or massive irreversible brain injury.^{73,74} Risk of irreversible neurologic injury is greatest in those with CPP less than 40 mm Hg for more than 4 hours. Lesser increases in ICP may be associated with neurologic injury, but usually cerebral edema resolves in the posttransplant period, and complete or partial neurologic recovery may be expected. In most cases of acute liver failure, all the manifestations of neurologic illness (cerebral edema, encephalopathy, and coma) reverse without sequelae following successful hepatic transplantation. One complication, central pontine myelinolysis, may occur in the absence of cerebral edema and may be related to fluctuations in plasma sodium during resuscitative measures in the ICU, such as IV fluids, transfusions, antibiotics, sedatives, narcotics, invasive procedures, and ventilatory support. Despite the

serious nature of central pontine myelinolysis, significant neurologic recovery can occur.

ENCEPHALOPATHY IN THE SETTING OF CHRONIC LIVER DISEASE

Patients with cirrhosis of any cause and chronic PSE may present with a host of neuropsychiatric symptoms, ranging from subtle changes in mental status to coma. Fetor hepaticus (a peculiar odor to the breath in people with severe liver disease) is common but not invariable. Asterixis, the “flapping tremor,” is due to involuntary intermittent relaxation of sustained motor activity but is less specific than fetor hepaticus for hepatic encephalopathy and is usually only present during the late stages of encephalopathy. Although reported, cerebral edema rarely occurs in patients with encephalopathy in the setting of chronic liver disease. As the patient recovers from hepatic encephalopathy, asterixis and other manifestations of encephalopathy resolve.

Risk Factors and Precipitating Events: Implications for Diagnostic Testing and Treatment

Flares of chronic encephalopathy may occur spontaneously without an identifiable precipitant in patients with very severe hepatic impairment and/or extensive portosystemic shunting. However, in the majority of cases, acute worsening of chronic encephalopathy is precipitated by one or more of a number of common events.

Gastrointestinal Hemorrhage

Hemodynamically significant gastrointestinal (GI) hemorrhage is a major precipitant of hepatic encephalopathy. Delivery of a large protein load to the GI tract via hemorrhage stimulates bacterial metabolism of luminal blood and release of NH_3 , GABA, and other chemicals or compounds that may inhibit neurotransmission. Poor hepatic function or shunting of portal blood via portosystemic collaterals impairs hepatic clearance and enhances delivery of these molecules to the brain.

Infection

Infection—in particular, sepsis—may precipitate hepatic encephalopathy in patients with chronic liver disease. Spontaneous bacterial peritonitis (SBP) always should be considered in the differential diagnosis of patients with ascites and new-onset encephalopathy. Fever may be absent, and clinical signs (abdominal pain, ileus) are lacking. SBP is presumptively diagnosed if the absolute neutrophil count in ascitic fluid exceeds 250 cells/mL. Patients with cirrhosis and malnutrition are susceptible to infections due to reduced leukocyte migration, decreased serum bactericidal activity, depressed white cell mobilization, and impaired phagocytosis. Infection increases protein catabolism, releasing aromatic amino acids that may contribute to the encephalopathy.

Medications (Sedatives)

There are no safe sedatives for administration in cirrhotic patients who have hepatic encephalopathy. Because liver metabolism is usually severely impaired in these patients, the clearance of benzodiazepines, barbiturates, chlorpromazine, morphine, and opioid derivatives such as methadone, meperidine, and codeine are reduced. With repeated dosing, all these compounds tend to accumulate in cirrhotic patients, increasing the degree and prolonging the duration of sedation.

Renal Failure

A common precipitant of hepatic encephalopathy is excessive diuresis, resulting in relative depletion of intravascular volume and prerenal azotemia. Factors contributing to the encephalopathy include electrolyte imbalances, disordered acid-base metabolism, reduced fluid volume, and impaired renal clearance of metabolites, drugs, and toxins.

Fluid, Electrolyte, and Acid-Base Imbalance

Hepatic encephalopathy may be precipitated by dehydration, hypokalemia, and alkalosis. Metabolic alkalosis promotes an increase in levels of nonionic NH_3 , which diffuses very rapidly into the CNS. Diffusion of NH_3 into the brain and enhanced glutamine production may precipitate encephalopathy due to either astrocyte swelling and dysfunction or impairment of glutamatergic neurotransmission. With hepatic impairment, the kidneys produce glucose from branched-chain amino acids (gluconeogenesis) in an attempt to maintain peripheral energy supply. This process results in decreased circulating levels of branched-chain amino acids and an increase in circulating levels of the relatively more toxic aromatic amino acids, which may diffuse into the brain.

Surgical Shunt Procedure or TIPS

Hepatic encephalopathy is a common complication of portal diversion following surgical portosystemic shunts or TIPS.⁷⁵ Predictors of post-shunt encephalopathy include preshunt encephalopathy, severe liver disease (Child-Pugh score >10 or Model-for-End-Stage-Liver-Disease [MELD] score >16), renal failure, and elderly age. The mechanisms of hepatic encephalopathy after placement of a portosystemic shunt include lack of compensatory dilatation of the hepatic artery, lack of perfusion of the liver via the portal vein, and reduction in hepatocyte function. Clinically apparent encephalopathy after placement of a shunt usually responds to medical treatment. In rare circumstances, narrowing of the shunt with a flow-reducing stent or occlusion of the shunt may be necessary to control encephalopathy.⁷⁶

Portosystemic Shunting from Collaterals

In cases of refractory encephalopathy, patients should undergo contrast-enhanced abdominal imaging to visualize the presence of prominent portosystemic collateral vessels. If large collaterals are seen, selected patients may benefit from embolization of these collaterals.^{77,78}

Noncompliance with Therapy

One of the most common factors precipitating encephalopathy is noncompliance with prescribed outpatient medical treatments (e.g., lactulose). A careful history, focusing on adherence to medical therapy, is necessary in the evaluation of encephalopathic patients.

Diagnosis

The diagnosis of PSE is based upon clinical suspicion in patients with chronic liver disease, and the impression is confirmed by resolution following medical therapy. Occasionally it may be necessary to employ additional testing to confirm a diagnosis of PSE. Additional testing is particularly useful when encephalopathy is the primary clinical manifestation of otherwise unsuspected liver disease or if the manifestations of encephalopathy are predominantly a change in behavior or an unusual neurologic syndrome (seizures, focal neurologic deficits). Rarely, cerebral edema complicates chronic liver disease.⁷⁹

Plasma Ammonia

An elevated blood NH_3 level is common in cirrhotic patients, especially those with encephalopathy. Some studies have demonstrated a correlation between blood NH_3 levels and the presence and grade of encephalopathy, while others have not. In general, blood NH_3 levels might be useful as a marker of liver disease but are of little diagnostic or clinical value in managing the cirrhotic patient with hepatic encephalopathy.

Electroencephalography

Electroencephalographic (EEG) abnormalities are relatively nonspecific in hepatic encephalopathy. Two findings have some specificity as regards hepatic encephalopathy: reduced brainstem auditory-evoked potentials and diminished visual-evoked potentials. In various studies, the percentage of encephalopathic cirrhotics with EEG abnormalities is highly variable, ranging from 14% to 78% of patients.

FIGURE 95-3 ■ Computed tomographic (CT) scan of the brain of a patient with acute liver failure, stage IV hepatic coma, and cerebral edema. Note the diminished sulci and lack of distinction between white and gray matter. This patient's cerebral edema resolved with medical management, and she subsequently underwent transplantation. She achieved complete neurologic recovery post transplant.

Radiologic Imaging

Standard CT scans or nuclear brain scans exhibit little or no specific distinguishing features, although loss of cortical volume may be common in patients with Laënnec's cirrhosis and chronic encephalopathy. CT may be used to document cerebral edema or to exclude CNS complications such as tumor, infection, or hemorrhage. Magnetic resonance imaging (MRI) studies have revealed a few features relatively unique to hepatic encephalopathy. One feature, hyperintensity on T_1 -weighted images of the globus pallidus (see Fig. 95-3), correlates with (extrapyramidal) motor disorders and excess accumulation of manganese.

Neuropsychiatric Testing

In general, neuropsychiatric testing is used primarily to monitor efficacy of treatment. A battery of tests is employed to distinguish hepatic encephalopathy and organic brain syndrome from other causes of encephalopathy and underlying psychiatric disease. These tests are itemized in Table 95-2. Poor performance on number connection tests correlates reasonably well with severity of encephalopathy and Child-Pugh and/or MELD classifications.

Therapeutic Options

Past thoughts on the treatment of hepatic encephalopathy included a protein-restricted diet of 40 grams or less per day.^{80,81} However, cirrhotic patients often develop severe muscle wasting; thus, in patients with advanced disease, unnecessary protein restriction might further worsen the poor nutritional state. Therefore, hepatologists currently avoid the use of protein restriction in the management of chronic hepatic encephalopathy.

Lactulose

The mainstay of therapy in the treatment of hepatic encephalopathy is lactulose, a nonabsorbable disaccharide that is fermented by bacteria in the intestine to yield acetic, butyric, propionic, and lactic acids.⁸¹⁻⁸³ The fermentation of lactulose produces an acidic milieu that alters the composition of gut bacterial flora, lowers colonic pH, and produces an osmotic diarrhea. Each of these effects may be responsible for the ameliorative effects of lactulose on hepatic encephalopathy. Changing

the composition of the bacterial flora may alter the metabolism of fecal contents and reduce the production of toxins, NH_3 , and methanethiols that are responsible for encephalopathy. The acidic luminal milieu creates an environment capable of trapping NH_3 :

Ammonia is neutral and freely diffuses across the mucosal barrier of the colon, where it can enter the portal circulation for delivery to the rest of the body. In contrast, the ammonium ion (NH_4^+) produced from the reaction of NH_3 with hydrogen ions is ionized, highly polar, and unable to diffuse readily across the lipid bilayer of mucosal cells. This ammonium ion is “trapped” in the fecal effluent and eliminated with passage of the bowel movement. In addition to these properties, the breakdown of each molecule of lactulose produces at least four osmotically active particles. Water diffuses into the lumen and down the osmotic gradient, increasing fecal water content, and if enough lactulose is given, a dose-dependent osmotic diarrhea results. The purgative effect of lactulose may also be responsible for altering the composition of colonic bacteria and helping to eliminate toxins and waste that might otherwise accumulate. The usual recommendation is that enough lactulose be given to produce two to three loose, semiformal stools each day. Excessive dosing with lactulose will produce severe diarrhea with large volume losses and electrolyte imbalances and should be avoided.

Rifaximin

Rifaximin is a nonabsorbable antibiotic derivative of rifamycin with broad antimicrobial activity and has become an important adjunct agent along with lactulose for the treatment of hepatic encephalopathy.⁸⁴ In comparison studies of rifaximin with lactulose, patients treated with rifaximin showed greater improvement in the degree of hepatic encephalopathy, had lower NH_3 levels, and had lower PSE index scores.⁸⁴ A randomized controlled trial of 299 patients demonstrated reduction of recurrent hepatic encephalopathy episodes and number of hospitalizations due to hepatic encephalopathy.⁸⁵

Branched-Chain Amino Acids

Early studies demonstrated that cirrhotic patients had an increase in aromatic amino acids and a decrease in branched-chain amino acids in blood samples. Subsequent clinical work suggested that patients with the greatest imbalance in plasma amino acids were more likely to

be encephalopathic and to experience early and higher mortality. For this reason, there have been at least 14 controlled trials of the use of branched-chain amino acids in the treatment of cirrhotic patients with chronic encephalopathy. However, results of these trials have been inconsistent, and separate meta-analyses have yielded opposite conclusions.⁸⁶ A trial of branched-chain amino acids might be considered in patients who develop encephalopathy on standard protein diets and manifest protein-calorie malnutrition.

Benzodiazepine Antagonists

There have been several randomized controlled trials of short-term administration of flumazenil in the treatment of hepatic encephalopathy.⁸⁷⁻⁸⁹ In some studies, flumazenil was superior to placebo in improving the grade of encephalopathy; 30% to 60% of encephalopathic patients improved after administration of flumazenil, and EEG changes paralleled this improvement. In other studies, however, flumazenil was no better than placebo in ameliorating the symptoms of encephalopathy, and EEGs did not improve. Overall, flumazenil has a limited role in the treatment of hepatic encephalopathy.

L-Ornithine-L-Aspartate (LOLA) and Ammonia Scavengers

L-ornithine-L-aspartate (LOLA) is a compound salt that was shown to reduce NH_3 levels by increasing NH_3 disposal through enhanced peripheral metabolism. LOLA increases the activity of hepatic urea cycle enzymes and also increases the rate of glutamine production within skeletal muscle. Although a large randomized controlled study using LOLA in acute liver failure did not find significant changes in survival,⁶² other studies investigated its potential use in hepatic encephalopathy from chronic liver disease. A meta-analysis consisting of three randomized trials and a pool of 212 patients found an overall significant improvement in chronic hepatic encephalopathy symptoms, although lower grade encephalopathic patients had the greatest benefit.⁹⁰

Additional agents (i.e., glycerol phenylbutyrate and ornithine phenylacetate) that were initially developed for ammonia reduction in patients with inborn urea cycle defects are also being tested in clinical trials for the management of chronic hepatic encephalopathy.^{91,92}

Neomycin

Another agent for second-line therapy of chronic hepatic encephalopathy is orally administered neomycin. Neomycin has a limited entrance to the circulation, with the goal of therapy being to alter the bacterial composition of the colonic flora.^{93,94} The main disadvantage is that nephrotoxicity may occur despite its poor absorption. Given the establishment of rifaximin, the use of neomycin has decreased substantially and it is now rarely used. If used in selected cases, it is recommended to give only short courses lasting 2-8 weeks.

Metronidazole

Studies have demonstrated that oral metronidazole (500 mg to 1.5 g/day given for 1 week) was as effective as neomycin or lactulose in controlling encephalopathy.⁹⁴ Others have not observed similar efficacy and have measured little effect of metronidazole on blood NH_3 levels. The advantages of metronidazole are that it does not cause diarrhea. A disadvantage is that many patients complain of epigastric discomfort with its use (leading to poor compliance with long-term treatment) and can develop ototoxicity as well as neurologic side effects that can be irreversible. Maintenance therapy can be expected to cause peripheral neuropathy (already a problem in patients with advanced liver disease), and metronidazole has been reported to cause the “disulfiram reaction” when alcohol is consumed. The physician prescribing metronidazole to cirrhotic patients also should be aware that this drug undergoes extensive hepatic metabolism. Given the establishment of rifaximin, the use of metronidazole for encephalopathy has decreased substantially and it is now rarely used. If used in selected cases, it is recommended to also only give short courses lasting 2-8 weeks to prevent toxicities.

Liver Transplantation

The development of encephalopathy in a patient with chronic liver disease indicates the presence of portosystemic shunting and hepatic dysfunction. The prognosis for patients who develop this complication is grim; one recent study indicated that the 1-year survival rate is 42% and the 3-year survival rate is 23%.⁹⁵ In addition, there are numerous comorbidities in encephalopathic patients, including inability to continue gainful employment, poor function at home, nursing strains on spouse or family, inability to drive a vehicle, and inability to handle personal finances. Although medical therapies can ameliorate the major symptoms of encephalopathy, they are rarely effective enough to return the patient to full function. Often the patient with encephalopathy is at risk of other life-threatening complications of liver disease such as variceal hemorrhage and spontaneous bacterial peritonitis. For all the above reasons, any patient with hepatic encephalopathy should be considered for hepatic transplantation.

CONCLUSION

This chapter has discussed several key issues regarding hepatic encephalopathy, including definitions, clinical syndromes, diagnostic tests, precipitants, prognosis, and outcomes with therapy including hepatic transplantation. The section on pathogenesis defines current knowledge regarding mechanisms of encephalopathy in both acute liver failure and chronic liver disease. The clinician faced with neuropsychiatric syndromes in patients with liver disease must differentiate the nature of the underlying liver disorder (acute liver failure versus chronic liver disease), evaluate diagnostic tests, and institute appropriate therapy. Overall outcomes of patients with encephalopathy depend on the general condition of the patient, severity of underlying liver disease, comorbid conditions, and when in acute liver failure, the

presence of cerebral edema and intracranial hypertension. Liver transplantation, including the option of living donor liver transplantation, may yield favorable outcomes without neurologic sequelae if instituted prior to excessive and prolonged intracranial hypertension in the case of acute liver failure, or prior to multiorgan failure in the case of chronic liver disease.

KEY POINTS

1. Clinical presentation and prognosis of hepatic encephalopathy vary by presence of acute liver failure or chronic liver disease.
2. Patients with high-grade hepatic encephalopathy (stage III or IV) and acute liver failure should urgently be referred to a liver transplant center.
3. The routine use of intracranial pressure monitors in patients with acute liver failure is controversial.
4. Mannitol and hypertonic saline are common therapies for intracranial hypertension in the setting of acute liver failure.
5. Precipitants of hepatic encephalopathy should be assessed with each episode in the setting of chronic liver disease.
6. Lactulose is the mainstay of therapy in patients with hepatic encephalopathy and chronic liver disease.
7. Rifaximin has become an important therapy to prevent recurrent episodes of hepatic encephalopathy in the setting of chronic liver disease.

Acute liver failure (ALF), also known as *fulminant hepatic failure* (FHF), includes a spectrum of clinical entities characterized by acute liver injury, severe hepatocellular dysfunction, and hepatic encephalopathy. Approximately 2000 people annually in the United States develop FHF, which has a high mortality rate.¹ Loss of hepatocyte function sets in motion multiorgan dysfunction syndrome, with ensuing death even when the liver has begun to recover. Complications of FHF include encephalopathy, cerebral edema, sepsis, acute respiratory distress syndrome (ARDS), hypoglycemia, coagulopathy, gastrointestinal bleeding, pancreatitis, and acute kidney injury (AKI). Acetaminophen toxicity, idiosyncratic drug reactions, and hepatotropic viruses remain the most common causes of FHF in the United States. FHF accounts for 5% to 6% of all liver transplantations, which is currently the only proven and definitive treatment option for patients who are unlikely to recover spontaneously. Unfortunately, many patients die before a suitable organ can be identified. Thus, the dominant medical interventions for ALF in the critical care setting are supportive. Alternative “liver replacement” therapeutic strategies are currently under clinical investigation.

DEFINITIONS

The terms *fulminant hepatic failure* and *acute liver failure* are often used interchangeably. FHF is defined as the presence of encephalopathy (regardless of grade) and coagulopathy (international normalized ratio [INR] > 1.5) within 26 weeks of the appearance of symptoms in patients with no previous history of underlying liver disease. Since the original definition of FHF proposed by Trey and Davidson in 1970, several other classifications have emerged (Box 96-1).²⁻⁶ In the different classifications, the interval between the onset of symptoms or jaundice and the appearance of encephalopathy allows grouping of patients with similar causes, clinical characteristics, and prognosis.

ETIOLOGY

Viral hepatitis remains the most common identifiable cause of FHF in the developing world, whereas acetaminophen toxicity and idiosyncratic drug reactions remain the most frequent apparent causes of FHF in the United States and Europe. Both prognosis and management are determined in part by the underlying etiology of FHF.

Acetaminophen Toxicity

Intentional or accidental acetaminophen overdose is the leading cause of FHF in the United States and accounts for 40% to 50% of cases.⁷ A careful medical history clarifies the quantity ingested; blood levels can be confirmatory but may not be elevated in cases of unintentional overdose. Doses considered nontoxic (<4 g/day in adults) may cause hepatotoxicity if other concurrent factors exist, such as alcohol ingestion, fasting, or malnutrition. Hepatotoxicity usually develops 1 to 2 days after the overdose, and circulating alanine aminotransferase (ALT) levels and INR values peak around day 3. Continued increase of INR after day 3 is associated with a poor prognosis. Although acetaminophen does not traditionally cause kidney injury, there are reports of nephrotoxicity in the case of overdose even in the absence of liver necrosis.⁸

Acetaminophen undergoes phase 1 metabolism by hepatic cytochrome P₄₅₀ 2E1 enzymes to a toxic intermediate compound, *N*-acetyl-*p*-benzoquinone imine (NAPQI), which is rapidly detoxified by hepatic

glutathione into a nontoxic metabolite. Under normal conditions, little NAPQI accumulates. However, in an overdose, owing to a depletion of the glutathione stores, unconjugated NAPQI accumulates, causing hepatocellular necrosis. The amount of liver injury is directly related to the amount of ingested acetaminophen and the amount of NAPQI produced. As a result, the ingested dose does not correlate with the overall prognosis.⁹ Enzyme inducers such as alcohol, antiepileptic drugs, and cigarette smoke can enhance acetaminophen-mediated hepatotoxicity.

Idiosyncratic Drug Reactions

Drug-induced liver damage is a significant cause of death in patients with FHF in Western countries (Box 96-2). The most common implicated drugs are antibiotics (amoxicillin-clavulanate, tetracyclines, and macrolides), antituberculosis drugs (isoniazid, pyrazinamide), anti-convulsants, antidepressants, nonsteroidal antiinflammatory drugs (NSAIDs), and halothane. The diagnosis of drug-induced liver injury should remain a diagnosis of exclusion.¹⁰ Dose, duration, and the hepatic metabolism of the drug all may play roles in the development of drug-induced liver injury. In the setting of FHF secondary to drug toxicity, all nonessential medications should be discontinued as soon as possible in the course.

Most idiosyncratic drug reactions are due to a single agent, but multiple medications can be implicated in some patients. Risk factors include sex, age, obesity, preexisting liver disease, and concurrent use of other hepatotoxic drugs. Most idiosyncratic reactions occur within 4 to 6 weeks after the initiation of treatment, although rare cases have occurred months or years later.

Idiosyncratic hepatic injury is mediated by several mechanisms, including the disruption of intracellular calcium homeostasis, injury to the canalicular transport pumps, such as multidrug resistance-associated protein 3, T cell-mediated immunologic injury, triggering of apoptotic pathways by tumor necrosis factor- α , and the inhibition of mitochondrial beta oxidation.¹¹

Hepatotoxic herbal medicines (kava kava, St. John's wort) and certain dietary supplements are emerging as potential causes in a high proportion of patients with FHF.¹² Mushroom poisoning due to *Amanita phalloides* ingestion is relatively common in Europe, and more sporadic cases occur in the United States. Florid muscarinic effects such as sweating or watery diarrhea occur early on, whereas FHF usually occurs 4 to 8 days after mushroom ingestion. Other toxins (e.g., carbon tetrachloride, yellow phosphorus, aflatoxins) are rare causes of FHF. The role of liver biopsy in the diagnosis of drug-induced liver injury is controversial and can be considered when associated with drugs not commonly implicated in liver injury and to exclude common conditions and assist with prognosis.¹⁰ Treatment with *N*-acetylcysteine (NAC) improves transplant-free survival compared with placebo and may be used in drug-induced liver injury.¹⁴

Viral Hepatitis

Viral hepatitis is an important cause of FHF worldwide. Although the development of FHF due to viral hepatitis is rare (0.2%-0.4% for hepatitis A, 1%-4% for hepatitis B), liver failure can occur because of the worldwide incidence of these viruses. Considerable geographic variation exists with regard to subtype: hepatitis B virus (HBV) is a common cause of FHF in the Far East, whereas hepatitis E virus (HEV) is more common in the Indian subcontinent,¹⁵ and most of the liver

BOX 96-1 Classifications of Acute Liver Failure**TREY AND DAVIDSON²**

Fulminant hepatic failure: development of HE within 8 weeks of onset of symptoms

BRITISH CLASSIFICATION⁶

Acute liver failure (includes only patients with encephalopathy)

Subclassification Depending on the Interval Between the Onset of Jaundice and HE

- Hyperacute liver failure: 0 to 7 days
- Acute liver failure: 8 to 28 days
- Subacute liver failure: 29 to 72 days
- Late-onset acute liver failure: 56 to 182 days

FRENCH CLASSIFICATION³

Acute hepatic failure: a rapidly developing impairment of liver function

Severe acute hepatic failure: prothrombin time or factor V concentration below 50% of normal with or without HE

Subclassification

- Fulminant hepatic failure: HE within 2 weeks of onset of jaundice
- Subfulminant hepatic failure: HE between 3 and 12 weeks of onset of jaundice

INTERNATIONAL ASSOCIATION FOR THE STUDY OF ACUTE LIVER FAILURE⁵

Acute liver failure (occurrence of HE within 4 weeks after onset of symptoms)

Subclassification

- Acute liver failure—hyperacute: within 10 days
- Acute liver failure—fulminant: 10 to 30 days
- Acute liver failure—not otherwise specified
- Subacute liver failure (development of ascites and/or HE from 5 to 24 weeks after onset of symptoms)

HE, hepatic encephalopathy.

transplants due to viral causes in the United States are caused by hepatitis A virus (HAV) and HBV.

HAV is associated with a higher risk of developing FHF if infection is acquired in older adulthood. Thus, vaccination is recommended for adults traveling from developed countries to endemic areas. The relevance of HAV as a cause of FHF in patients with preexisting chronic liver disease has been recognized, and HAV vaccination has been suggested for this high-risk group. Postexposure prophylaxis with immune serum globulin may reduce the incidence of HAV infection but only when administered within 14 days of exposure.

HBV can result in FHF through several mechanisms: acute primary HBV infection, reactivation of HBV in patients with chronic HBV infection, or superinfection with hepatitis D virus (HDV). Acute HBV infection is diagnosed by the detection of immunoglobulin M (IgM) antibodies against hepatitis B core antigen (HbcAg). A substantial number of patients have negative serum hepatitis B surface antigen (HBsAg) and serum HBV DNA. Patients with low or absent levels of HBsAg and HBV DNA typically have a better prognosis and lower rate of recurrence after orthotopic liver transplantation (OLT). FHF after reactivation of chronic hepatitis B has been described mainly in immunosuppressed patients and is usually associated with a subfulminant course and a poor prognosis. Hepatitis C virus infection alone does not typically result in FHE, although cases have been reported.¹⁶

FHF is observed in 2.5% to 6% of HDV cases. Coinfection with HBV and HDV or superinfection by HDV in patients with chronic hepatitis B can also cause FHE. The incidence of coinfection is higher when intravenous (IV) drug abuse is present. Diagnosis of acute infection by HDV is made by the presence of HDV antigen, anti-HDV IgM antibody, or HDV RNA.

Infection by HEV is uncommon in Western countries but can occur in travelers to endemic areas. Pregnant women infected by HEV are more likely to develop FHE. Diagnosis is made by the detection of anti-HEV IgM antibodies.

Other viruses are implicated in the pathogenesis of FHF (Box 96-2).

Reye syndrome

Other Etiologies

Cardiovascular, metabolic, and other disorders account for 2% to 10% of cases of FHF. Acute liver ischemia secondary to shock states can result in hepatocellular necrosis; however, the prognosis remains good if the primary condition is corrected. The prognosis is worse when FHF is due to other causes such as the acute form of Budd-Chiari syndrome, veno-occlusive disease, or malignancies associated with impaired hepatic blood flow. The first manifestation of Wilson's disease is rarely FHF, although the typical disease course is chronic. Acute fatty liver of pregnancy is rare, occurring in the third trimester of pregnancy, and usually improves with fetal delivery. Other rare causes of FHF are autoimmune hepatitis, non-Hodgkin's lymphoma, heat stroke, or Reye syndrome.

PROGNOSTIC SCORING SYSTEMS

Survival in patients with FHF depends on many factors, including etiology, age, the severity of the liver dysfunction, the degree of liver necrosis, the nature of the complications, and the duration of illness. Patients with grade IV encephalopathy have a higher than 80% mortality rate without OLT. The successful use of OLT in FHF has created a need for early prognostic indicators to select the patients who are the most likely to benefit. Various prognostic scoring systems exist (Box 96-3). Many of these are subject to debate because they equate death with liver transplant, which falsely elevates the positive predictive value of any prognostication method.¹⁷

BOX 96-3**Various Prognostic Criteria Used for Liver Transplantation in Patients with Fulminant Hepatic Failure****KING'S COLLEGE CRITERIA¹⁸****Acetaminophen Overdose**

- Arterial pH < 7.3 (irrespective of grade of encephalopathy)
- or
- PT > 100 s (INR > 6.5) and
- Serum creatinine > 3.4 mg/dL (>300 μmol/L) and
- Patients with grade III and IV hepatic encephalopathy

Non-Acetaminophen-Induced Liver Injury

Acute form (delayed jaundice-encephalopathy <7 days):

- PT > 100 s (INR > 6.5) (irrespective of grade of encephalopathy) or any three of the following variables:
- Aged <10 or >40 years
- Non-A, non-B hepatitis, halothane hepatitis, idiosyncratic drug reactions
- Subacute form: delayed encephalopathy >7 days
- Serum bilirubin 17.4 mg/dL (300 μmol/L)
- PT > 50 s

LIVER BIOPSY²²

70% necrosis is discriminant of 90% mortality

Gc, plasma group-specific component protein; INR, international normalized ratio; PT, prothrombin time.

For patients with acetaminophen overdose, HAV infection, shock liver, or pregnancy-related ALF, the short-term survival rate without transplantation is over 50%. The short-term transplant-free survival rate is lower (<25%) for patients with FHF of indeterminate cause or FHF caused by other factors such as drugs other than acetaminophen, HBV infection, autoimmune hepatitis, Wilson's disease, Budd-Chiari syndrome, or cancer. The King's College prognostic criteria are the most widely used both in cases of acetaminophen-induced and non-acetaminophen-induced FHF (Box 96-3). These criteria provide a reasonable prediction of the likelihood of death and the need for transplantation in FHF patients.¹⁸

Other approaches include the Clichy criteria,¹⁹ which use factor V assay, factor VIII/V ratio, serial α -fetoprotein levels, and plasma group-specific component protein (Gc globulin) levels.²⁰ Liver volume decreases with the progression of the disease, and its measurement with computed tomography (CT) may help assess the prognosis. Other proposed markers for poor prognosis include serum levels of phosphate above 1.2 mmol/L on day 2 or 3, blood lactate concentration over 3.0 mmol/L, or a Model for End-stage Liver Disease (MELD) score higher than 32.^{21,22} An alternate scoring system, the Acute Liver Failure Study Group index, which is composed of a combination of clinical markers and measurements of the apoptosis biomarker M30, has been shown to better predict outcomes compared with the King's College Criteria or the MELD score.²³

ROLE OF LIVER BIOPSY

Liver biopsy can confirm the suspected cause of FHF and determine the degree of hepatocyte necrosis. Greater than 70% necrosis in a liver biopsy specimen is associated with a 90% mortality rate without transplantation.²⁴ Because coagulopathy precludes safe percutaneous liver

biopsy, the transjugular approach is often preferred. Liver biopsy can help exclude occult malignancy, provide etiologic information, and assess the liver for evidence of regeneration.

PATHOGENESIS AND CLINICAL FEATURES OF ALF

FHF is clinically distinct from chronic hepatic insufficiency, regardless of the etiology. The constellation of symptoms typically involves non-specific symptoms such as malaise and nausea, followed by jaundice, rapid onset of altered mental status, and coma. Altered mentation and a prolonged INR are the hallmarks of the diagnosis. Supportive laboratory findings include high aspartate transaminase/ALT levels, elevated total bilirubin concentration, low serum glucose levels, and arterial blood gas studies showing metabolic acidosis and/or respiratory alkalosis. Patients with subfulminant hepatic failure have a more gradual onset of hepatic insufficiency accompanied by ascites, renal failure, and a very poor prognosis.

The magnitude of the elevation of aminotransferase levels and the rate of decline do not affect the prognosis. When patients spontaneously recover, the serum bilirubin concentration and INR normalize, whereas when the disease progresses, bilirubin levels continue to increase (due to intrahepatic cholestasis), and INR remains prolonged despite declining ALT levels. The high mortality rates associated with FHF are caused by complications such as cerebral edema, renal failure, sepsis, pancreatitis, and cardiopulmonary collapse.

Encephalopathy

Encephalopathy differentiates FHF from acute severe hepatitis. The onset of encephalopathy is often abrupt and, occasionally, may precede the appearance of jaundice. Agitation, delusion, and hyperkinesia are common but short-lived symptoms; coma rapidly ensues. The overall prognosis for those with stable grade I/II encephalopathy is good, whereas the prognosis for patients with grade III/IV encephalopathy is poorer. In cases of acetaminophen overdose, encephalopathy usually occurs on the third or fourth day after ingestion and rapidly progresses to grade IV within 24 to 48 hours.

The pathophysiology of hepatic encephalopathy is likely caused by astrocyte swelling and cerebral edema due to the synergistic effects of excess ammonia and inflammation, although the precise underlying molecular mechanisms are unclear.^{25,26} Newly synthesized glutamine is transported from the cytoplasm into the mitochondria and is metabolized by glutaminase, yielding glutamate and ammonia. The generation of ammonia in the small mitochondrial compartment may reach extremely high levels, leading to the induction of mitochondrial permeability transition, production of free radicals, and potential oxidative damage of the mitochondrial constituents. Elevated serum ammonia concentration is exacerbated by decreased urea synthesis in the injured liver.²⁷ Endogenous substances, false neurotransmitters, short-chain fatty acids, benzodiazepines, and γ -aminobutyric acid are additional factors that can lead to encephalopathy.

The electroencephalogram (EEG) typically shows diffuse slowing of cortical activity and high-amplitude waveforms at 5 to 7 cycles per second. Subclinical seizure activity is often present in patients with grade III or IV encephalopathy, emphasizing the importance of EEG monitoring in these patients. Prophylactic therapy with phenytoin has been shown to reduce both seizure activity and cerebral edema.²⁸

Cerebral Edema

Cerebral edema is estimated to occur in 75% to 80% of patients who progress to grade IV encephalopathy and is the leading cause of death in these patients. The mechanism(s) responsible for cerebral edema are not completely understood but likely include cerebral hyperemia, vasogenic edema due to disruption of the blood-brain barrier, and cytotoxicity due to the osmotic effects of ammonia, glutamine, and other amino acids, as well as the deleterious effects of proinflammatory

cytokines and dysfunction of the sodium-potassium ATPase pump, with loss of autoregulation of the cerebral blood flow.^{29,30}

Intracranial blood flow is markedly reduced in patients with chronic hepatic encephalopathy; the decrease in perfusion appropriately matches the reduction in cerebral metabolic rate (CMR). Patients with FHF often develop either relative or absolute cerebral hyperemia; therefore, perfusion is often not well matched to the reduced CMR present in evolving or established hepatic coma. An early indicator of this pathologic process is either a decrease in the transcranial oxygen content difference (arterial oxygen content – jugular bulb oxygen content) to less than 4 mL/dL or an increase in the systolic blood flow velocity of the middle cerebral artery. Serial transcranial Doppler ultrasonographic monitoring of cerebral blood flow velocity helps in the detection of early cerebral hyperperfusion or hypoperfusion suggestive of impaired cerebral autoregulation.^{31,32} Cerebral ischemia and permanent neurologic sequelae may occur if cerebral perfusion pressure (CPP), calculated as the mean systemic arterial blood pressure minus intracranial pressure (ICP), is not maintained above 40 to 50 mm Hg. CT of the brain often fails to demonstrate cerebral edema in patients with elevated ICP. The late clinical stages of cerebral edema include systemic hypertension, decerebrate rigidity, hyperventilation, pupillary dilation, seizures, and brainstem herniation. An arterial ammonia level above 200 µg/dL in grade III and grade IV encephalopathy is a strong predictor of brain herniation.³³ Full recovery of cerebral function is usually expected following the return of normal liver function; however, permanent brain damage can occur.

Coagulopathy

Severe coagulopathy is typical of FHF due to impaired hepatic synthetic function leading to the inadequate production of coagulation factors. Decreased levels of factors II, V, VII, IX, and X account for the prolongation of prothrombin time and later, activated partial thromboplastin time. In addition to coagulopathy, there also exists a tendency for thrombosis due to a decreased production of anticoagulation factors such as proteins C and S and a decreased clearance of activated coagulation factors by the liver. Disruption of the balance between procoagulant and anticoagulant factors may result in excessive thrombosis and disseminated intravascular coagulation, which can be difficult to confirm with laboratory testing. Coagulopathy is often complicated by thrombocytopenia, with platelet counts below 100,000/µL in two-thirds of patients.

Metabolic Derangements

FHF results in a myriad of metabolic abnormalities. Hypoglycemia is reported in up to 45% of patients with FHF due to the depletion of hepatic glycogen stores and impaired gluconeogenesis, which is often refractory to the infusion of IV dextrose solution. Hepatic insulin resistance and impaired peripheral insulin sensitivity may also be present.³⁴ Lactic acidosis is common in acetaminophen-induced FHF and has a poor prognosis. Hyponatremia, alkalosis, hypokalemia, and hypophosphatemia are also common, and ionized hypocalcemia may indicate concomitant pancreatitis. Acute renal failure is seen in 30% to 70% of patients with ALF due to a combination of factors such as intravascular volume depletion, acute tubular necrosis (ATN), or direct nephrotoxicity from ingested drugs such as acetaminophen or NSAIDs. Adrenal insufficiency has been described in up to 62% of patients with FHF.³⁵

Cardiovascular, Hemodynamic, and Respiratory Complications

Circulatory dysfunction accompanying FHF often mimics sepsis. Typically, patients are hyperdynamic with low systemic vascular resistance due to the proinflammatory effects of circulating endotoxins and cytokines. Patients with hypotension despite adequate volume resuscitation should be started on norepinephrine infusion. Cardiac arrhythmias frequently occur because of electrolyte imbalances as well as increased

circulating levels of catecholamines (from endogenous release or deliberate infusion). Severe peripheral shunting has been observed in FHF and may result from the plugging of small vessels by platelets, interstitial edema, or abnormal vasomotor tone. An abnormal pattern of oxygen supply dependency results in oxygen extraction over a wider than normal range of oxygen delivery, presumably as a compensatory mechanism.

Hyperventilation, hypocapnia, and respiratory alkalosis occur during ALF and may worsen encephalopathy. Arterial hypoxemia is nearly universal and is caused by a combination of intrapulmonary shunting, ventilation/perfusion mismatching, sepsis, aspiration, and ARDS.

Sepsis

FHF is associated with impaired host resistance to and enhanced susceptibility to bacterial and fungal infections. Common infections are aspiration pneumonia and primary bloodstream infections, including fungal infections. The most common microbial pathogens are gram-positive bacteria (*Staphylococcus aureus*, enterococci), enteric gram-negative bacilli (*Escherichia coli*, *Klebsiella* spp.), and *Candida* spp. Diminished hepatic reticuloendothelial function and opsonic activity, defective polymorphonuclear leukocyte function, and impaired cell-mediated and humoral immunity are the major predisposing mechanisms. Periodic surveillance cultures for bacterial and fungal infections are recommended. In one prospective study of 50 patients, 80% had culture-proven infection, with suspected infection in half of the remaining patients.³⁶

MANAGEMENT

Patients with FHF are best cared for in an intensive care unit. Transfer to a liver transplantation center should be considered at the time of admission.

Therapy Directed at the Specific Etiology of FHF

Depending on the suspected etiology, a number of therapies exist that can ameliorate or reverse the degree of liver injury. NAC should be administered to all patients with FHF, regardless of the cause. NAC is a specific antidote for acetaminophen overdose; it replenishes glutathione stores and prevents the development of hepatotoxicity if given within the first 8 to 10 hours after an acute overdose. Administration of NAC within 8 hours is associated with a significantly improved survival rate but may be effective up to 72 hours after acetaminophen ingestion.³⁷ IV NAC is preferred over the enteral route. Although some experts recommend continued treatment until the INR normalizes, prolonged NAC therapy in mice has been shown to impair liver regeneration following acetaminophen poisoning.³⁸

Benefits of NAC on survival, brain edema, hemodynamics, oxygen delivery, and oxygen consumption have been found in patients with established FHF.³⁷ A randomized, controlled trial of NAC by the U.S. Acute Liver Failure Study Group in patients with non-acetaminophen-induced FHF showed an improved transplant-free survival rate.¹⁴ For patients with known acetaminophen overdose within 4 hours of presentation, the administration of activated charcoal prior to starting NAC is recommended.

Hepatitis secondary to HSV may be missed because of its nonspecific presentation and the absence of typical mucocutaneous lesions. Most patients with HSV hepatitis are immunosuppressed hosts. If HSV hepatitis is suspected, treatment with parenteral acyclovir or ganciclovir should be started.

Treatments of other conditions causing FHF vary in terms of success and evidence supporting their use. Wilson's disease can be managed temporarily with plasma exchange, which can remove relatively large amounts of copper in a short period of time. However, plasmapheresis only helps to bridge patients to transplant and carries no survival

benefit. Chelating agents such as penicillamine are ineffective in the setting of FHF due to Wilson's disease. Hemofiltration and albumin dialysis may also be considered as temporizing measures before OLT.^{39,40}

FHF due to autoimmune hepatitis has a variable course, as conventional immunosuppressive therapy with high-dose steroids has been observed to be effective in 20% to 100% of patients with fulminant presentation. These patients should be considered for transplantation even while steroids are being administered.⁴¹ While the exact role of corticosteroids or immunosuppressive agents in the management of FHF due to autoimmune hepatitis has not been well established,⁴² it is recognized that patients who do not respond to treatment after 2 weeks are more likely to die without liver transplantation. Acute fatty liver of pregnancy usually responds to fetal delivery, with improved mortality rates with early delivery. Urgent chemotherapy is indicated for FHF caused by massive infiltration of the liver by lymphoma. Acute Budd-Chiari syndrome may be amenable to thrombolytic therapy or to transjugular intrahepatic portosystemic shunt placement.

Hepatic Encephalopathy

The treatment of encephalopathy is directed at limiting gut ammonia production and the avoidance of aggravating factors such as infection, ileus, obstipation, gastrointestinal hemorrhage, and other central nervous system depressants. Endotracheal intubation for grade III and IV hepatic encephalopathy is usually indicated. Lactulose may be useful in the treatment of patients with grade I or II encephalopathy; however, administration of lactulose does not improve survival in advanced encephalopathy. The efficacy of lactulose in FHF has not been tested in clinical trials. This agent should be used with caution because of the risk of hypernatremia, dehydration due to diarrhea, and the potential for bowel distention. Lactulose by enema remains an option in FHF patients who are unable to tolerate oral or nasogastric administration.

Oral metronidazole, neomycin, and rifaximin directed against ammonia-producing gut flora have been employed. However, metronidazole may be neurotoxic in hepatic failure, and neomycin, although minimally absorbed, can still cause nephrotoxicity and ototoxicity. Rifaximin is effective at decreasing ammonia levels due to hepatic encephalopathy, with good evidence for its use in chronic liver failure, and should be considered as an adjunct to lactulose in treating encephalopathy in FHF. Endogenous benzodiazepine-like substances have been identified in the cerebrospinal fluid of patients with hepatic encephalopathy. Flumazenil, a benzodiazepine receptor antagonist, has been used with some success to provide short-term improvement in patients with hepatic encephalopathy.⁴³ Administration of L-ornithine-L-aspartate in patients with FHF was found to be ineffective at reducing circulating ammonia levels or improving survival and may cause increased seizure activity. L-Ornithine phenylacetate remains a potential temporary agent for the treatment of hepatic encephalopathy while awaiting transplant; however, it has yet to be validated in humans.⁴⁴

Cerebral Edema

The optimal management of cerebral edema requires maintaining the delicate balance between mean arterial pressure and ICP to preserve adequate cerebral perfusion (Box 96-4). Cerebral edema combined with intracranial hypertension is the most common cause of death in patients with FHF whose ICP is above 30 mm Hg. An arterial ammonia level over 200 µg/dL predicts brain herniation.³³ ICP monitoring may help to diagnose intracranial hypertension and guide management, especially in grade III or IV encephalopathy, although its use has not been shown to decrease mortality.^{45,46} ICP should be maintained below 20 mm Hg, and CPP should be maintained above 50 mm Hg, although transplant-free recovery has been reported in acetaminophen-induced FHF patients despite impaired cerebral perfusion for 2 to 72 hours.⁴⁷ Most centers prefer epidural to subdural or intraparenchymal transducers for monitoring ICP because of the lower rates of hemorrhagic and infectious complications.^{45,48} Monitoring

BOX 96-4

Preventive and Therapeutic Interventions for Patients with Cerebral Edema and Intracranial Hypertension

GENERAL MEASURES

Head-of-bed elevation to 30° and maintenance of the patient's neck in a neutral position
Endotracheal intubation for grade III or IV hepatic encephalopathy
Minimize tactile and tracheal stimulation, including airway suctioning
Avoid hypovolemia and hypervolemia
Avoid hypertension
Avoid hypercapnia and hypoxemia
Monitor and maintain ICP < 15 mm Hg
Maintain CPP > 50 mm Hg
Monitor and maintain SvjO₂ between 55% and 85%
Use serial transcranial Doppler monitoring to titrate therapy

MANAGEMENT OF INTRACRANIAL HYPERTENSION

Mannitol boluses, 0.5-1.0 g/kg body weight
Hyperventilation titrated to a PCO₂ of 28-30 mm Hg
Induced moderate hypothermia to 32°C-33°C
Achieve serum sodium levels of 145-155 mEq/L
Induced coma with propofol or pentobarbital titrated to burst suppression of 5-10 cycles/s
CVVH for oliguria and hyperosmolarity (>310 mOsm/L)

OTHER UNPROVEN THERAPIES

Prophylactic phenytoin
Indomethacin, 25 mg intravenous bolus
Plasmapheresis
Total hepatectomy as a bridge to transplant

CPP, cerebral perfusion pressure; CVVH, continuous veno-venous hemofiltration; ICP, intracranial pressure; SvjO₂, jugular bulb oxygen saturation.

jugular bulb oxygen saturation with a reversed jugular bulb venous catheter also can guide interventions to avoid or treat intracranial hypertension. Decreased venous oxygen saturation (<55%) indicates cerebral ischemia, whereas high venous oxygen saturation (>85%) indicates either decreased metabolic demands of the brain or cerebral hyperemia (more commonly the latter).³²

Current recommendations include maintaining the patient's head at midline and a 30-degree upright angle to improve jugular venous outflow. In episodes of intracranial hypertension, a bolus of 0.5 to 1 g/kg of mannitol can be administered IV and repeated until the plasma osmolarity reaches 310 mOsm/L. Patients with oliguria and renal failure may require hemodialysis to avoid hyperosmolarity. Corticosteroids should not be used to control cerebral edema associated with FHF.

Hyperventilation reduces cerebral blood flow by 2% to 3% for every millimeter of mercury reduction in PaCO₂. Moderate hyperventilation (PaCO₂ = 28-30 mm Hg) can be employed to reduce ICP, but not all patients respond to reductions in PaCO₂, and the efficacy of hyperventilation wanes after 48 hours. Excessive cerebral vasoconstriction can be detected as widening of the difference in the cerebral arteriovenous oxygen content. Serial transcranial Doppler studies help detect early changes in cerebral blood flow in response to therapy.³² Induction of mild to moderate hypothermia (core temperature 34°C-35°C), which can be induced with cooling blankets or a special intravascular catheter, has been shown to reduce ICP and cerebral blood flow and improve CPP in patients with FHF awaiting transplant who do not respond to osmotic agents for the management of ICP.⁴⁹ Care must be taken to avoid both cardiac depression and shivering during the induced hypothermia. Induction of a barbiturate coma by administering parenteral sodium pentobarbital, sodium pentothal, or propofol titrated to the appearance of 5 to 10 cycles per second of EEG burst suppression can further reduce both CMR and cerebral blood flow in refractory patients. However, adverse effects such as myocardial depression or arterial hypotension may create the need for inotropic or vasopressor support to preserve CPP in the minimally adequate range. In patients at high risk for cerebral edema with high ammonia levels, grade III/IV encephalopathy, and renal failure despite the use of vasopressors, the use of a

hypertonic saline to induce hyponatremia to maintain a serum sodium concentration of 145–155 mEq/L is recommended.⁵⁰

Indomethacin may be used when cerebral hyperemia is present, as it has been shown to reduce cerebral blood flow and prevent brain edema in experimental models of FHF.⁵¹ Prophylactic infusion of phenytoin has been studied in two controlled studies that reached different conclusions.⁵² Phenytoin in the absence of seizures is not recommended.

Coagulopathy

Despite severe coagulopathy, patients with FHF seldom experience spontaneous hemorrhage. Since the INR is important to the prognostic evaluation, routine use of fresh frozen plasma (FFP) is not recommended unless spontaneous bleeding occurs or an invasive procedure is planned. Administration of FFP does not increase the survival rate and may cause intravascular volume overload and worsen cerebral edema, in addition to the potential risk of developing transfusion-related acute lung injury. Platelets may be transfused before invasive procedures if the platelet count is less than 50,000 cells/ μ L. When evaluation of the patient's mental state is not possible, monitoring coagulation parameters helps clinicians to assess the improvement or worsening of liver function.

AKI

AKI develops in up to 70% of patients with FHF, and the presence of FHF and renal failure has a grave prognosis without renal support. Mechanisms include renal hypoperfusion, ATN due to systemic inflammatory response syndrome (SIRS), hepatorenal syndrome, and direct toxic effects of the etiologic agent responsible for the liver injury (e.g., acetaminophen). The presence of SIRS predicts renal failure in non-acetaminophen-induced FHF.⁵³ Monitoring of serum creatinine and urinary output is essential. Diuretics and “renal dose” dopamine have no protective value in the treatment of acute renal failure and are potentially harmful. Nephrotoxic drugs such as aminoglycosides or radiographic contrast agents should be avoided. Continuous venovenous hemofiltration is preferred over intermittent hemodialysis in order to avoid rapid fluid shifts and abrupt changes in ICP.⁵⁴

Miscellaneous Therapy

Glycemic control is vital in the management of FHF. Constant infusion of glucose is preferable to bolus administration for the maintenance of euglycemia. FHF is a catabolic state, and nutrition should be started soon and adjusted individually to maintain an adequate caloric intake. Enteral nutrition through a nasogastric or nasojejunal tube is preferred to parenteral nutrition. Gastrointestinal prophylaxis is usually indicated.

A high index of suspicion should be maintained for the presence of infection, because fever and leukocytosis are absent in up to 30% of infected patients. Infection must be suspected in the presence of any sudden clinical deterioration, such as worsening encephalopathy or hemodynamic instability, especially when liver function has started to recover.⁵⁵ Microbiological cultures should be obtained from appropriate sites, and empirical antibiotics covering both enteric gram-negative and gram-positive bacteria should be started. Antifungal coverage should be considered, particularly in patients already on broad-spectrum antibacterial coverage with new-onset clinical deterioration. Unless there is high suspicion for bacterial infection, prophylactic antibiotics are not recommended.^{36,56}

Hepatic Replacement Therapies

Liver Transplantation

FHF accounts for about 5% to 10% of liver transplants performed in the United States. OLT, along with advances in critical care support, has dramatically improved the survival rate of FHF. However,

BOX 96-5

Hepatic Replacement Therapeutic Options Available to Patients with Fulminant Hepatic Failure

LIVER TRANSPLANTATION

- Cadaveric transplantation
- Whole liver
- Reduced size liver
- Split liver
- Auxiliary partial or whole liver
- Orthotopic position
- Heterotopic position
- Living-related transplantation
- Left lateral segment
- Left lobe
- Extended left lobe
- Right lobe

ARTIFICIAL LIVER ASSIST DEVICES

- Non-cell-based systems
- Charcoal hemoperfusion
- High-volume plasmapheresis
- Continuous high-frequency hemodiafiltration
- Molecular adsorbent recirculating system
- Cell-based systems (bioartificial liver assist devices)
- Primary porcine hepatocytes
- Human hepatoblastoma cells
- Extracorporeal liver assist device

HEPATOCYTE TRANSPLANTATION

transplantation is high risk, with a lower 1-year survival rate than those transplanted for other causes due to poor clinical condition at the time of the procedure. Contraindications to transplantation include irreversible brain damage, uncontrolled infection, severe pancreatitis, and malignancy. Early identification of patients who are likely to survive without OLT using both the King's College and the Clichy criteria is essential (Box 96-3). Liver biopsy, although not mandatory, can help clinicians decide the need for early transplantation. In general, patients with $\leq 60\%$ necrosis are likely to survive without the need for transplantation, whereas those with $\geq 90\%$ necrosis are unlikely to survive without transplantation.^{18,19} The prognosis without transplantation is less clear for patients in between these boundaries.

Various surgical options exist for liver transplantation in patients with FHF (Box 96-5). The most frequently utilized procedure is cadaveric whole organ transplantation, with the donor organ being placed in the orthotopic position. However, continued efforts are being made to assess ways of expanding the donor pool by using marginal donors, living-donor liver transplantation, cadaveric split-liver transplantation, and various hepatic support systems to prolong survival long enough for the patient to undergo liver transplantation. Therapeutic hepatectomy with temporary portocaval anastomosis in FHF has been reported to stabilize FHF patients until a suitable liver donor organ was procured.^{58,59}

Other Replacement Therapies

The use of artificial and bioartificial liver support devices in FHF has been shown to improve the biochemical and physiologic indices of liver function, although they have not been shown to improve transplant-free or overall survival.⁶⁰ Hepatocyte transplantation has been attempted in patients with FHF to maintain liver function until the regeneration of the native liver occurs or a graft for organ transplantation becomes available. Experimental studies in models of FHF have shown engraftment, function of transplanted hepatocytes, and increased survival.⁶¹ Future trials using this concept are needed.

CONCLUSION

FHF remains a rare but devastating illness with a high mortality rate. The treatment of FHF poses a great challenge to intensive

care clinicians. Early transfer to a transplant center is preferable not only because of the availability of transplantation but also because of the availability of experienced clinicians. A multidisciplinary approach to critical care management is required to address the multitude of organ derangements. Currently, only liver transplantation can radically alter the course of the disease process.

Although transplant surgery including immunosuppressive therapy has considerably advanced over the past decade, this intervention is expensive and is associated with complications related to both the procedure and the need for lifelong immunosuppression. Liver replacement therapies require further validation of their safety and efficacy.

KEY POINTS

1. Fulminant hepatic failure (FHF) is distinguished from severe acute hepatitis by the presence of hepatic encephalopathy. Without liver transplantation, the mortality rate for FHF is 50% to 80%.
2. Acetaminophen overdose remains the dominant cause of FHF in the United States. The hepatotoxic effects of acetaminophen are potentiated by concurrent alcohol ingestion, glycogen depletion, and/or anticonvulsant medication use.
3. The King's College Criteria remain the most widely used prognostic scoring system for FHF; however, failure to fulfil the criteria does not reliably predict survival.
4. The onset of grade III or IV hepatic encephalopathy prognosticates a higher risk for mortality. The onset of grade III or IV encephalopathy is an indication for endotracheal intubation and the performance of diagnostic and therapeutic modalities for intracranial hypertension.
5. Intracranial hypertension is the major cause for early mortality in FHF and is due to cerebral hyperemia, osmotic factors, and derangements of the blood-brain barrier.
6. Cerebral hyperemia can be detected by a decrease in the cerebral arteriovenous oxygen content difference or by transcranial Doppler showing elevated systolic blood flow velocity.
7. Elevated intracranial pressure can be managed with hyperventilation, mannitol administration, mild hypothermia, therapeutic sedation, and other less proven interventions; however, the optimal management of this condition remains unknown.
8. Prophylactic administration of fresh frozen plasma does not improve survival and may aggravate volume overload and cerebral edema.
9. Continuous veno-venous hemofiltration is the preferred method for artificial renal replacement to avoid hemodynamic fluctuations, which can aggravate cerebral hyperperfusion or hypoperfusion.
10. Liver transplantation is the only proven liver replacement therapy to reduce mortality. It remains unproven whether both biological and nonbiological artificial liver replacement therapies can reduce transplant-free mortality.

Evaluating the patient with a possible acute abdomen in the intensive care unit (ICU) can be challenging. Patients frequently have multiple potential sources of sepsis and are often unable to describe symptoms or localize tenderness on physical examination. In addition, many imaging studies require transporting the patient to the radiology suite, which can be risky. These issues are especially troublesome for patients with potential acute cholecystitis.

Acute cholecystitis, frequently without gallstones, has long been recognized as a complication of surgery or acute critical illness.¹ The pathophysiology of cholecystitis in critically ill patients is different from that in the general population, as at least half of the patients have no gallstones.² Understanding the risk factors and pathogenesis of acute cholecystitis can help increase the index of suspicion and lead to early diagnosis and treatment, which is necessary for good outcomes in the already critically ill patient.

RISK FACTORS AND PATHOPHYSIOLOGY

In the general population, acute cholecystitis is associated with the presence of gallstones, which develop as a result of decreased solubility of cholesterol and bile salts in bile. Risk factors for gallstones include age, female sex, recent pregnancy, positive family history for gallstones, and hemolysis. Patients with gallstones may develop acute cholecystitis at any time. Rarely, acute calculous cholecystitis can occur during hospitalization for other reasons.

Acalculous cholecystitis can occur spontaneously under certain circumstances. In outpatients, risk factors for acalculous cholecystitis include diabetes mellitus, vasculitis, older age, and male sex.³ Acalculous cholecystitis also has been reported in cancer patients and patients with systemic infections. Acute cholecystitis is the most common indication for exploratory laparotomy or laparoscopy in patients with acquired immunodeficiency syndrome.⁴ Most have acalculous disease. Not surprisingly, the mortality rate is high.

In children, the majority of cases of acute cholecystitis are acalculous.⁵ The etiology appears to be dehydration or lymphadenopathy secondary to viral infection. Congenital biliary tract anomalies should also be considered.

Acute cholecystitis has been described in multiple reports as a complication of a variety of surgical procedures,^{6,7} trauma,^{8,9} burns,¹⁰ sepsis,¹¹ cardiovascular diseases, and malignancy.¹² There is also an association between total parenteral nutrition and biliary stasis.^{13,14} The pathophysiology of this association, however, remains unclear.

Theories regarding the pathogenesis of acalculous cholecystitis in critically ill and postoperative patients have evolved over the years. Presumptive causes have included gastrointestinal hypomotility, biliary stasis, and lack of enteral feeding in the postoperative period, leading to increased concentrations of bile salts and cholesterol in bile.¹⁵ The rarely observed acute onset of cholecystitis with refeeding suggests impaction of stones or viscous bile in the cystic duct with gallbladder contractions.

Gallbladder mucosal necrosis, arterial thrombosis, gangrene, and perforation suggest that hypoperfusion may be another critical mechanism for acalculous cholecystitis. Histopathologic studies confirm microvascular changes and ischemic cholecystitis histologically.^{16,17} Hypoperfusion, particularly of the splanchnic circulation, is common in critically ill patients. Etiologic factors include hemorrhage,

dehydration, heart failure, and sepsis. The use of vasopressors can exacerbate the situation. Mechanical ventilation with positive end expiratory pressure can increase hepatic venous pressure and thereby decrease portal perfusion.¹⁸

In addition to hypoperfusion, increased intraluminal pressure may be a critical factor.¹⁹ Biliary stasis secondary to fasting and narcotics may increase intraluminal pressure in the gallbladder. The combination of hypoperfusion and increased intraluminal pressure leads to gallbladder perfusion pressure decrease, wall ischemia, bacterial invasion, and cholecystitis.

The use of parenteral nutrition has also been implicated in the pathogenesis of acalculous cholecystitis. In addition to the effects of fasting, parenteral nutrition can directly decrease bile production, worsening biliary stasis. Biliary sludge can be found in almost all patients on long-term parenteral nutrition.^{14,15} Many go on to form gallstones. Trauma patients also develop sludge over time, which may play a role in the development of cholecystitis, as well as pancreatitis.²⁰

Other suggested etiologies include eosinophilic infiltration of the inflamed gallbladder resulting from a hypersensitivity reaction to antibiotics administered for other reasons²¹ and pigment load from massive transfusions.¹⁸ Neither theory has been substantiated.

INCIDENCE

The incidence of acute cholecystitis in the ICU is difficult to determine, given the great diversity in ICU patient populations and illness severity. Among cardiac surgical patients, acute cholecystitis, half of which is acalculous, is second only to upper gastrointestinal hemorrhage as an indication for abdominal surgery.²² Visceral hypoperfusion related to left ventricular dysfunction has been implicated as an etiologic factor. Early predictors of acute cholecystitis include arterial occlusive disease, low preoperative oxygen delivery, longer cardiopulmonary bypass times, need for surgical reexploration, cardiac arrhythmias, mechanical ventilation for ≥ 3 days, bacteremia, and nosocomial infections.⁶ The common threads among these factors include decreased tissue perfusion and oxygenation, significant surgical trauma with the expected inflammatory response, and perhaps bacterial translocation from the gut lumen. Because of high risk, some have suggested ultrasound screening in patients with complicated courses after cardiovascular surgical procedures.⁷

In the general population of postoperative patients, acute cholecystitis appears to occur with or without gallstones. Mortality is about 30%. Among trauma patients, about 90% of the acute cholecystitis cases are acalculous.^{8,9} The percentage of acute cholecystitis cases that are acalculous has increased significantly over time. Because the incidence of the disease is low but the many risk factors for the disease are common, it is difficult to identify specific groups of ICU patients who might benefit from selective screening for acute cholecystitis.

CLINICAL PRESENTATION

The signs and symptoms of acute cholecystitis do not generally differ between calculous and acalculous disease. Typically, patients with acute cholecystitis present with right upper quadrant or epigastric pain, often associated with ingesting a fatty meal. The pain may radiate to the back. Anorexia, nausea, and vomiting are common findings, as

are fever and chills. If the patient is receiving enteral nutrition, the symptoms may be related to meals or tube feedings.

On examination, the most consistent finding is fever. Focal tenderness in the right upper quadrant or epigastrium is typically found, often with evidence of peritoneal irritation. Rarely, the gallbladder is palpable. There may be abdominal distention and loss of bowel sounds. Jaundice may be present if the patient develops choledocholithiasis, Mirizzi's syndrome (external compression of the common hepatic duct by a stone impacted in the cystic duct), or liver dysfunction from sepsis. In critically ill patients, symptoms and physical examination findings are frequently difficult to assess or absent because of alterations in the patient's mental status and concurrent disease.

The most consistent laboratory finding is a leukocytosis. Circulating levels of liver enzymes and bilirubin are usually normal without choledocholithiasis, Mirizzi syndrome, or sepsis. Clinical findings and laboratory studies are not very sensitive or specific for cholecystitis, even in the general population,²³ and are less so in critically ill patients.

Given that the underlying pathophysiology of cholecystitis in the ICU often involves gallbladder wall ischemia, there is significant risk for rapid progression to gangrene and perforation. Consequently, even though other causes of sepsis in the ICU are more common, one needs to have a low threshold for considering cholecystitis in the differential diagnosis of patients who may have intraabdominal sepsis. Imaging of the gallbladder should be the next step.

IMAGING STUDIES

Ultrasonography is an accurate radiologic test and is usually the first test of choice for acute cholecystitis in the general population and in critically ill patients. In the ICU, the presence or absence of gallstones does not help with the diagnosis. The most useful ultrasonographic findings are thickening of the gallbladder wall and pericholecystic fluid (Fig. 97-1). These findings correlate well with operative findings. False positive findings may occur with sludge, nonshadowing stones, cholesterosis, ascites, hypoalbuminemia, and portal hypertension. Other ultrasonographic findings indicative of acute cholecystitis include the following: the "double wall sign," representing edema of the gallbladder wall; the "halo sign," representing sloughed gallbladder mucosa; intramural gas; distention of the gallbladder; and the "sonographic Murphy's sign," demonstrating point tenderness on physical examination over the gallbladder. The sensitivity of ultrasound for detecting acalculous cholecystitis is 81% to 92%. The specificity is 60% to 96%,²³⁻²⁶ but these results are operator dependent.

One problem in the ICU is that the typical ultrasonographic findings of cholecystitis can be seen in ICU patients without other evidence of cholecystitis. For example, Boland et al. performed ultrasound examinations of the gallbladder twice a week in a variety of ICU patients.²⁴ Half of the patients without calculi developed at least one ultrasonographic finding of acute cholecystitis. Helbich et al. attempted to apply a scoring system to the ultrasonographic findings characteristic of acute cholecystitis, suggesting that patients with several findings should undergo more aggressive diagnostic evaluation and, perhaps, therapeutic interventions.²⁵ In equivocal cases, serial examinations may demonstrate increasing wall thickness, which should increase the suspicion for cholecystitis.²⁶

Scintigraphy of the gallbladder frequently has been used when acute cholecystitis is suspected but findings from other tests such as ultrasound are inconclusive or contradictory. Gallbladder scintigraphy is performed by administering technetium-labeled iminodiacetic acid (IDA). Cholecystitis is diagnosed if the radioactive tracer is visualized in the small bowel without visualization of the gallbladder within 4 hours, suggesting occlusion of the cystic duct (Fig. 97-2). Delayed visualization of the gallbladder may represent chronic cholecystitis. The rate of false positive tests is significant in fasting patients, particularly those receiving parenteral nutrition, as the gallbladder may already be maximally filled. The use of intravenous morphine to increase tone in

FIGURE 97-1 ■ Ultrasound of the gallbladder demonstrating wall thickening (double arrows) and sludge (black arrow).

FIGURE 97-2 ■ Scintigraphy of the biliary tree demonstrating concentration of the tracer in the liver followed by flow into the biliary tree and small bowel. The gallbladder is not visualized.

the sphincter of Oddi and thereby increase pressure within the biliary system can decrease the risk of a falsely positive test.²⁷ In patients with severe liver disease, there may be inadequate uptake and excretion of the tracer to provide visualization of the biliary tree. Also, if a patient has had a biliary sphincterotomy, the tracer may pass too quickly through the biliary tree. Overall, the sensitivity of scintigraphy is 91% to 97%, and the specificity is 38% to 99%.²⁷⁻²⁹ Scintigraphy is a useful complement to ultrasonography for early decision making regarding intervention,^{28,29} but all clinical findings should be considered.

Computed tomography (CT) of the abdomen can be used to make the diagnosis of acute cholecystitis.^{30,31} The criteria for a positive study include wall thickness >4 mm, pericholecystic fluid, intramural gas, sloughed mucosa, or subserosal edema without ascites (Fig. 97-3). If intravenous contrast is administered, enhancement of the gallbladder wall may be seen. Although CT may not be as sensitive as the other studies for determining the presence of gallstones or acute cholecystitis, it can help to detect or rule out other causes of an acute abdomen. A great disadvantage of CT for critically ill patients, however, is the need to transport the patient to the scanner. In critically ill patients with suspected cholecystitis, ultrasound remains the first test of choice. Frequently, however, additional studies are necessary.

The differential diagnosis for patients with potential cholecystitis in the ICU includes peptic ulcer disease (particularly perforation), acute pancreatitis, hepatic or subphrenic abscess, pyelonephritis, right lower

lobe pneumonia (although right lower lobe atelectasis is common with a subdiaphragmatic process), and practically any cause of sepsis. The clinical presentation, laboratory studies, and imaging studies all should be considered when making clinical decisions.

To help with confirming the diagnosis of acute cholecystitis, the Tokyo Guidelines for the management of cholecystitis from 2013 (TG13) include specific criteria.³² Patients have suspected cholecystitis if they have signs of local inflammation (right upper quadrant pain, tenderness or mass, or a positive Murphy's sign) and signs of systemic inflammation (fever, elevated C-reactive protein, leukocytosis). The diagnosis is definitive if the patient has positive imaging studies. The severity of cholecystitis is defined as mild (without any of the "moderate" criteria), moderate (white blood cell count >18,000/mm³, palpable tender mass in the right upper quadrant, duration of symptoms >72 hours, or marked local inflammation), and severe (end-organ dysfunction).

MANAGEMENT

The management of a patient with acute cholecystitis involves supportive care, antibiotics, and either drainage or removal of the gallbladder (Fig. 97-4). Even in equivocal cases, drainage of the gallbladder may be appropriate in critically ill patients.

The standard initial medical treatment for acute cholecystitis includes antibiotics, analgesia, and, at least during the early phase, bowel rest. For patients who are septic from cholecystitis, it is appropriate to follow the Surviving Sepsis Campaign guidelines regarding fluid resuscitation, use of vasopressors, and initiation of broad-spectrum antibiotics.³³

Antibiotics for uncomplicated cholecystitis should cover enterococcal species and gram-negative rods, particularly *Escherichia coli* and *Klebsiella* spp.³⁴ Cultures are positive in about half the cases, more so beyond 72 hours after the onset of symptoms. If these patients undergo early cholecystectomy, continuing antibiotic coverage postop may not be necessary. In patients who have more severe illness or have previously received antibiotics, more resistant and unusual organisms are often cultured from gallbladder bile. These organisms can include *Staphylococcus* spp., resistant gram-negative bacilli, anaerobic bacteria, and fungi. Older patients are also more apt to have infected bile with more resistant organisms. In patients with empyema of the gallbladder, Tseng et al. found that bile cultures were positive in 83% of the cases.³⁵ Gram-negative bacteria (e.g., *E. coli*, *K. pneumoniae*, *Morganella morganii*, *Pseudomonas aeruginosa*, and *Salmonella* spp.) were found in 75%, gram-positive bacteria (e.g., *Enterococcus* spp.) in 30%, and obligate anaerobes in 7%. Broader coverage may be required initially until cultures are obtained and coverage can be more tailored, particularly in patients who have been exposed to antibiotics recently or who are immunosuppressed. Local antibiograms can be helpful.

FIGURE 97-3 ■ Computed tomographic study of the abdomen demonstrating thickening of the gallbladder wall with infiltration of the pericholecystic fat (black arrow) and gallstones (white arrow).

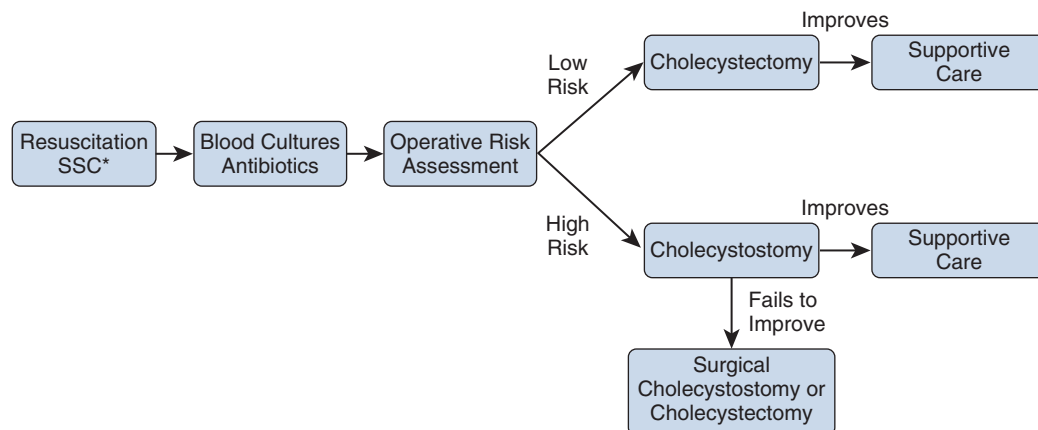

FIGURE 97-4 ■ Management of cholecystitis. *SSC, Surviving Sepsis Campaign.

Nonsteroidal antiinflammatory drugs can be very effective for controlling the pain from cholecystitis. When narcotics are needed, the choice of narcotic analgesic is probably not as important as was once believed. All narcotics can increase the pressure of the sphincter of Oddi, potentially increasing pressure in the biliary tree. Between these agents, there do not seem to be any important differences in pain relief or resolution of symptoms.

The next question is whether to drain or remove the gallbladder acutely. There is a lack of prospective, randomized trials to help clarify this issue. Early surgical consultation is critical. The decision regarding radiographic or surgical intervention must be made with consideration of both the critical care and general surgical issues. If the patient can tolerate transport to the operating room and a general anesthetic, cholecystectomy remains the most definitive therapy, particularly in light of the risk of gallbladder gangrene and perforation. Yacoub et al. have developed a scoring system for risk of gangrenous cholecystitis.³⁶ The 6.5-point scoring system is based upon the findings of age > 45 years (1 point), heart rate > 90 beats/min (1 point), male (2 points), white blood cell count > 13,000/mm³ (1.5 points), and gallbladder wall thickness > 4.5 mm on ultrasound (1 point). Frequently, however, critically ill patients with acute cholecystitis, particularly those with significant respiratory dysfunction or hemodynamic instability, may be too ill for cholecystectomy. With advances in the ease of image-guided drainage, bedside cholecystostomy using ultrasonographic guidance has been performed more commonly.

Image-Directed Drainage

Image-directed cholecystostomy was first used for palliation of obstructive jaundice in 1979.³⁷ The first large series of percutaneous cholecystostomy for acute cholecystitis was reported in 1985.³⁸ Of 114 patients, 113 were treated successfully.

Some physicians have used percutaneous cholecystostomy as a diagnostic and therapeutic maneuver in ICU patients with persistent, unexplained sepsis.³⁹ Many of these patients improved, though few had positive bile cultures. Thus, in critically ill patients without a definitive diagnosis of acute cholecystitis, the role of percutaneous cholecystostomy and bile culture remains unclear. Since the risk of this procedure is low, percutaneous cholecystostomy should be considered when the index of suspicion for acute cholecystitis is high enough in a critically ill patient.

Percutaneous cholecystostomy is contraindicated if the patient has evidence of diffuse peritonitis, suggesting gallbladder perforation. On the other hand, if imaging studies suggest a pericholecystic abscess, concomitant drainage of the abscess or surgical exploration is indicated.

Percutaneous cholecystostomy is performed under ultrasound or CT guidance. A needle is inserted into the gallbladder, usually via a transhepatic approach. The tract is dilated using a standard Seldinger technique. A pigtail catheter is advanced over the wire into the gallbladder. Some use a trocar technique instead. The catheter is then attached to a drainage bag.

Van Sonnenberg et al. reported successful percutaneous cholecystostomies in 125 of 127 patients with a variety of indications for the procedure.⁴⁰ Eleven patients (8.7%) had major complications, including bile peritonitis, bleeding, vagal reactions, hypotension, catheter dislodgment, and acute respiratory distress. Five (3.9%) had minor complications. No deaths were related to the procedure itself. Even in the presence of anticoagulation, the procedure seems to have relatively low risk.⁴¹

Overall mortality for percutaneous cholecystostomy is about 10%, similar to open cholecystectomy.⁴¹⁻⁴⁴ The limiting factor for success of percutaneous drainage is the viability of the gallbladder. Focal ischemia or necrosis is unlikely to improve without cholecystectomy and predisposes the patient to perforation. Cholecystectomy should be considered in patients who do not improve with cholecystostomy.

In many cases, cholecystostomy may provide definitive management without the need for interval cholecystectomy.^{43,44} Atar et al.

reported on a series of 81 patients with sepsis from acute cholecystitis and high anesthetic/surgical risk who underwent percutaneous cholecystostomy.⁴⁴ The procedure was successful in all cases. For patients with acalculous disease, the catheter was removed once the patient's symptoms resolved. This approach differs from the traditional recommendation for keeping the cholecystostomy in place for 6 weeks. Use of a transhepatic approach makes earlier removal safe. These patients did not undergo cholecystectomy. For patients with stones, a cholangiogram was performed. If common duct stones were found, the cholecystostomy access was used to perform a dilatation of the papilla. The stones were then pushed into the duodenum. All survivors with calculous disease underwent interval laparoscopic cholecystectomy.

A novel technique for drainage of the gallbladder involves a transpapillary endoscopic approach.⁴⁵ This approach may be helpful if other indications for endoscopic evaluation or intervention are present. It seems that the intervention is more successful if the ultrasound demonstrates that the gallbladder is not severely distended or thick.⁴⁶ Endoscopic ultrasound can also be used for transgastric or transduodenal placement of a stent into the gallbladder.⁴⁷

Surgical Management

Surgical options include cholecystostomy and cholecystectomy. Surgical cholecystostomy can be accomplished via a small right subcostal incision using local anesthesia or via laparoscopy. This procedure largely has been supplanted by image-guided, percutaneous cholecystostomy.

Cholecystectomy may be advantageous compared to cholecystostomy, since it allows one to examine the entire right upper quadrant for other pathology and to completely drain any fluid collections around the gallbladder. It also alleviates the risk of gallbladder perforation. When cholecystectomy is performed, a laparoscopic approach can usually be attempted, recognizing that one may need to abandon the attempt and proceed with an open procedure because of difficulty with the dissection. The timing of cholecystectomy for acute cholecystitis remains controversial.⁴⁸ On the other hand, if the patient is not responding to nonoperative management, cholecystectomy needs to be considered. If a patient improves after cholecystostomy, it may be beneficial to delay the cholecystectomy for at least 2 weeks.

Bedside laparoscopy can be performed for evaluation of the acute abdomen in critically ill patients. If acute cholecystitis is identified, a cholecystostomy can be performed readily or the patient can be taken to the operating room for a cholecystectomy.^{49,50} If the diagnosis of cholecystitis is excluded, the patient may be spared an unnecessary trip to the operating room.

Summary of Management

Early, supportive care for critically ill patients with cholecystitis should focus on resuscitation of the patient. The next steps are based upon the severity of cholecystitis (see Fig. 97-4). For patients at low risk for an operation, early laparoscopic cholecystectomy is recommended. For patients at high risk, urgent gallbladder drainage is more appropriate. If the patient fails to improve, operative intervention should be considered.

COMPLICATIONS AND OUTCOME

Complications of acute cholecystitis are much more common in critically ill patients than in the general population. Elderly patients are particularly at risk. Among patients with acalculous cholecystitis, gangrene is common.^{8-11,23} Compared to patients without gangrene, those with gangrene are at greater risk of perforation or of failure of percutaneous drainage. Some of these patients have emphysematous cholecystitis (gas in the wall of the gallbladder), a diagnosis that carries an even greater risk of perforation. Emphysema can be identified by plain abdominal radiographs, CT, or ultrasound. In these cases, antibiotics should cover gas-forming anaerobic organisms. Although

percutaneous drainage may be effective, early cholecystectomy is indicated if the patient does not improve promptly.

Perforation of the gallbladder occurs in up to 10% of cases.^{8-11,51} Usually, the resulting fluid collection is localized and amenable to percutaneous drainage. Free perforation also can occur, and when it does, the risk of mortality is markedly increased.⁵² The clinical problem, however, is that preoperative imaging may not demonstrate evidence of perforation.⁵³ The risk of perforation increases with delay in drainage or operation. Cholecystectomy is indicated for free perforation.

Empyema of the gallbladder also greatly increases mortality.⁵⁴ This complication may be amenable to percutaneous drainage, but the risks of failure or perforation are substantial.

The risk of mortality from cholecystitis in the ICU mainly reflects the underlying disease processes and comorbidities. Overall mortality is around 30%.⁸⁻¹¹

PREVENTION

No intervention has been shown conclusively to prevent development of cholecystitis in ICU patients. If the theories regarding the pathophysiologic mechanisms are correct, the incidence of the disease should be reduced by aggressively resuscitating patients with shock, avoiding biliary stasis by implementing early enteral feeding, and minimizing the use of narcotics. Intermittent doses of cholecystokinin or deoxycholic acid have been shown to increase bile flow and, therefore, may decrease the risk of acalculous cholecystitis in patients receiving parenteral nutrition,^{55,56} though studies in ICU patients are needed.

SUMMARY

The diagnosis of acute cholecystitis in critically ill patients is difficult because patients frequently do not present with the usual symptoms and signs. Laboratory tests are nonspecific. The best initial radiographic study is ultrasound. Scintigraphy and CT also may be helpful. Management includes antibiotics and bowel rest. Percutaneous cholecystostomy may be preformed in unstable patients, although cholecystectomy remains the most definitive treatment if this intervention can be accomplished safely.

KEY POINTS

1. Critically ill patients frequently do not present with the usual symptoms and signs of cholecystitis.
2. Laboratory tests for cholecystitis are not specific.
3. The best initial imaging study is ultrasound, but scintigraphy or computed tomography may be needed as well.
4. Management begins with antibiotics and bowel rest.
5. While cholecystectomy is the most definitive procedure, image-guided, percutaneous cholecystostomy is indicated for patients too unstable to undergo cholecystectomy.

The term *acute pancreatitis* describes a wide spectrum of disease ranging from a mild edematous form of acute pancreatitis to severe acute necrotizing pancreatitis. It is the most common gastrointestinal disease requiring hospitalization in the United States and accounts for annual costs of more than \$2 billion.^{1,2} The mild form of acute pancreatitis is a self-limited disease associated with minimal organ dysfunction; it has a mortality rate of less than 1% and usually resolves in 3 to 4 days. Patients with this form of acute pancreatitis rarely need intensive care unit (ICU) therapy or pancreatic surgery. Although most (80%) patients with acute pancreatitis have mild disease, 10% to 15% develop the systemic inflammatory response syndrome (SIRS) and run a fulminant clinical course leading to pancreatic necrosis and multisystem organ injury.^{3,4} The mortality rate for severe acute pancreatitis is 15% to 30%, whereas the overall mortality rate for all patients presenting with acute pancreatitis is less than 5%.^{3,4}

The first 7 to 14 days of this disease process are characterized by SIRS and resulting end organ dysfunction. Inflammatory mediators are released into the systemic circulation, and patients manifest signs and symptoms of cardiorespiratory and renal failure.⁵ Pancreatic infection is uncommon during this early phase, but bacteremia and pneumonia have been identified at a median of 7 days.⁵ Attempts to modify the course of the disease by instituting therapy with protease inhibitors, octreotide, or platelet-activating factor receptor antagonists have been unsuccessful.^{6,7}

Since the 1980s, the morbidity and mortality associated with acute pancreatitis have decreased substantially. Most cases of pancreatitis that result in patient death are related to infection.⁸ Infection of the necrotic pancreas (and associated tissues) typically develops in the second and third weeks of the disease and is reported to occur in 40% to 70% of patients with pancreatic necrosis.^{5,7,8} Infected necrosis is the most important risk factor for death secondary to necrotizing pancreatitis. Prevention, diagnosis, and optimal treatment of infection in severe acute pancreatitis are crucial for improving outcome for patients with this disease.

This chapter discusses the etiology, pathophysiology, severity and staging, and management of patients with severe acute pancreatitis.

ETIOLOGY AND EPIDEMIOLOGY

Overall rates of hospitalization for acute pancreatitis in the United States have increased to more than 274,000, making it the most common gastrointestinal cause requiring hospitalization.¹ The increasing incidence of acute pancreatitis is believed to be related to increases in alcohol consumption and gallstone disease. Acute pancreatitis is slightly more common in men than in women, with a female-to-male ratio of 1:1.2 to 1:1.5. Hospitalization rates and emergency department visits for patients diagnosed with acute pancreatitis are higher for blacks than for whites. Pancreatitis can occur in any age group, but cases in the very young (<3 years) are likely to be related to a systemic disease such as cystic fibrosis. On the other hand, alcohol-related acute pancreatitis has a peak incidence between 45 and 55 years of age, with a gradual decline thereafter. Biliary pancreatitis is more common in women, and alcohol-related acute pancreatitis is more common in men.

Understanding the etiology of a particular case of pancreatitis is important; evaluation and treatment depend to some extent on the

predisposing disease process. Gallstones are the leading cause of acute pancreatitis in developed countries and account for 35%-40% of all cases.⁹ It is also the most common form of pancreatitis in older patients, probably related to the increased prevalence of cholelithiasis in this age group.

Alcohol abuse typically accounts for about 30% of cases of acute pancreatitis. Infrequent causes of pancreatitis include drug reactions (usually idiosyncratic), pancreatic and ampullary tumors, hypertriglyceridemia, hypercalcemia, choledochal cysts, trauma (including acute pancreatitis after endoscopic retrograde cholangiopancreatography), and infectious or parasitic organisms. Rare causes include bites of certain spiders, scorpions, and the Gila monster lizard. Unidentified causes are termed *idiopathic*.

PATHOGENESIS AND GENETIC SUSCEPTIBILITY

Regardless of the etiology, pancreatitis is an inflammatory process that can initiate SIRS.⁵ The exact intracellular mechanisms initiating and accelerating pancreatitis are not completely understood. Three phenotypic responses occur in the acinar cell in the early phases of acute pancreatitis: (1) changes in secretions, (2) intracellular activation of proteases, and (3) generation of inflammatory mediators.¹⁰ Shortly after an appropriate stimulus, secretions are released from the apical cells into the pancreatic duct. This process entails exocytotic fusion of zymogen granules with the apical plasma membrane; the granules do not fuse with the basolateral membrane. However during acute pancreatitis, there is (1) markedly decreased apical secretion from the acinar cell, (2) disruption of the paracellular barrier in the pancreatic duct with leakage of contents into the paracellular space, and (3) redirection of secretion from zymogen granules to the basolateral regions of the acinar cell. Inappropriate activation of the proteolytic enzyme, trypsin, is thought to be the initial step in the development of acute pancreatitis. Trypsinogen activation is promoted by cationic trypsinogen mutations (PRSS1+), active trypsin, high calcium ion concentration, and low pH. Calcium levels are regulated in part by calcium-sensing receptors (CASR) and dysregulated by ethanol.^{5,11-13} If trypsin is active within the pancreas, inflammation results and this upregulates the serine protease inhibitor Kazal type 1 (SPINK1) gene, which further blocks activation of trypsinogen. Trypsin also activates cells via the trypsin receptor present in acinar and duct cells, known as *protease-activated receptor 2 (PAR-2)* (Fig. 98-1).¹⁴ Trypsin activity in the pancreas is controlled mainly by the pancreatic secretory trypsin inhibitor (PSTI), also called SPINK1.¹⁵ PSTI, a potent natural inhibitor of trypsin, is synthesized in pancreatic acinar cells. When trypsinogen is cleaved to release trypsin in the pancreas, PSTI immediately binds to the enzyme to prevent further activation of additional pancreatic enzymes. PSTI also blocks further activation of pancreatic cells via the trypsin receptor, PAR-2.¹¹

Several additional protective systems prevent pancreatic autodigestion by trypsin, and the genetic expression of these systems may contribute to the risk of developing acute pancreatitis or modulate the severity of the disease when it occurs.^{11,12,15} A mutation in SPINK1, N34S, has been reported in people with familial pancreatitis, in children with idiopathic chronic pancreatitis, and in 2% of the control population.^{11,13} Because these mutations in SPINK1 are much more

FIGURE 98-1 ■ Activation pathways of proenzymes and protease-activated receptor (PAR)-2 by trypsin. Trypsin activates many digestive proenzymes and inflammatory cells (via PAR-2). Trypsin activity in the pancreas is mainly controlled by pancreatic secretory trypsin inhibitor (PSTI). When trypsinogen is activated into trypsin in the pancreas, PSTI immediately binds to trypsin to prevent further activation of pancreatic enzymes.

common than pancreatitis, this mutation is probably a disease modifier rather than a causative factor of acute pancreatitis.

■ **DIAGNOSIS**

Acute pancreatitis can be diagnosed when a patient presents with acute upper abdominal pain and tenderness, nausea, vomiting, and hyperamylasemia or hyperlipasemia.¹⁶ These signs are nonspecific and can be present in other acute intraabdominal conditions. The Cullen sign and the Grey Turner sign (periumbilical and flank bruising, respectively) are rare and can be present with any cause of retroperitoneal hemorrhage. Although hyperamylasemia is common in patients with acute pancreatitis, normal circulating amylase levels can be present in 10% to 20% of all cases, predominantly in those secondary to hyperlipidemia, acute exacerbations of chronic pancreatitis, and those that present late in the course of the disease.¹⁷ Advantages of serum amylase determination include its technical simplicity, wide availability, and sensitivity. It does, however, have a low specificity. Serum lipase can also be found to be elevated in acute pancreatitis. Its concentration increases within 4 to 8 hours, peaks at 24 hours, and returns to normal after 8 to 14 days.¹⁸ The major advantage of serum lipase determination as a diagnostic test is its excellent sensitivity in acute alcoholic pancreatitis. It is also valuable when patients present to an emergency department days after the onset of the disease, as it remains elevated longer than amylase.¹⁸ Simultaneous estimation of amylase and lipase levels does not improve accuracy of diagnosis of acute pancreatitis.¹⁸

Serum triglyceride levels should be determined when an etiology of pancreatitis is uncertain and lipemic serum is suspected. While it has never been proven, circulating triglyceride levels above 1000 mg/dL (11.3 mmol/L) are believed to trigger pancreatitis.

Trypsinogen-2 can be used for diagnosing acute pancreatitis. It is measured via a urine dipstick assay (urinary trypsinogen-2-UT2), using a threshold of 50 µg/L.¹⁷ It has a reported sensitivity and specificity of 80% and 92%, respectively, at identifying patients with acute pancreatitis.¹⁷

■ **SEVERITY AND SCORING**

Prediction of the severity of the disease at the time of admission can be difficult. Several different prognostic scoring systems with clinical, laboratory, and radiologic criteria have been proposed, yet none of the proposed scoring systems has a high sensitivity, specificity, positive predictive value, or negative likelihood ratio, and frequent clinical assessment is essential for identifying patients with severe disease. Ranson's criteria (Table 98-1),¹⁹ the Imrie²⁰ (Glasgow) score, the Acute Physiologic and Chronic Health Evaluation (APACHE) II and III

| TABLE 98-1 Ranson's Criteria for Patients with Non-Gallstone-Associated Pancreatitis | |
|--|-------------------------------------|
| AT PRESENTATION | DURING INITIAL 48 HOURS |
| Age > 55 years | Hematocrit fall > 10% |
| White blood cell count > 16,000/µL | Blood urea nitrogen > 5 mg/dL |
| Blood glucose > 200 mg/dL | Serum calcium < 8 mg/dL |
| Serum alanine transferase > 250 U/dL | Arterial PO ₂ < 60 mm Hg |
| Serum lactate dehydrogenase > 350 IU | Base deficit > 4 mEq/L |
| | Estimated fluid sequestration > 6 L |

Modified from Blamey SL, Imrie CW, O'Neill J, Gilmour WH, Carter DC. Prognostic factors in acute pancreatitis. *Gut* 1984;25:1340-6.

scores,²¹ the simplified acute physiology score, and Balthazar's computed tomography (CT) index are the most popular scoring systems and are often used to determine the need for admission to an ICU. Ranson's criteria is based on 11 prognostic signs present at presentation and 48 hours later.¹⁹ A meta-analysis of studies using the Ranson criteria reported the following with regard to predicting severe acute pancreatitis (SAP): sensitivity, 74%; specificity, 77%; positive predictive value, 49%; and negative predictive value, 91%. Many institutions routinely utilize the APACHE scoring system for all patients admitted to the ICU.²¹ Patients with SAP and an APACHE II score above 8 have severe disease and are likely to develop organ failure. Key statistical parameters related to APACHE II scores of above 7 and the prediction of SAP are as follows: sensitivity, 65%; specificity, 76%; positive predictive value, 43%; and negative predictive value, 89%. Balthazar's CT index^{22,23} uses both fluid collections and amount of pancreatic necrosis to predict outcomes. An international group of experts concluded that an additional group of patients should be identified: those with moderately severe acute pancreatitis (MSAP).²⁴ In 2012, Talukdar et al. performed a prospective study in which patients were classified as having SAP, MSAP, or mild acute pancreatitis. The MSAP group had intervention rates and hospital stays comparable to those patients with SAP; however, only 12% required ICU care and none of them died, suggesting that this is a separate entity that should be identified early in order to determine prognosis.²⁴

There are several serum biomarkers that have been studied as predictors of the severity of acute pancreatitis. C-reactive protein (CRP) levels above 150 mg/L are associated with pancreatic necrosis

(sensitivity and specificity of 80%); however there is a 48-hour latency period before CRP increases, limiting its utility as an early predictor of disease.²⁵ Procalcitonin levels higher than 3.8 ng/mL can predict pancreatic dysfunction (sensitivity 79%, specificity 93%).²⁶

The scoring systems mentioned help quantify the degree of illness, but it is essential that clinicians identify patients with impending or actual organ failure. Patients with signs of SIRS are especially at risk of further organ dysfunction.

The Atlanta Classification system was initially published in 1993 and grouped pancreatitis into different categories in an attempt to determine severity.²⁷ It was revised in 2012 and groups patients into interstitial edematous pancreatitis and necrotizing pancreatitis: those who have diffuse inflammation of the pancreas and surrounding tissue are considered to have the former, while those with necrotic glands will be grouped as having necrotizing pancreatitis.^{27,28} The Atlanta Classification system also grades presentation into mild acute pancreatitis (no organ failure and no local or systemic complications), moderately severe acute pancreatitis (organ failure that resolves within 48 hours, local or systemic complications without persistent organ failure), and severe acute pancreatitis (persistent organ failure).^{27,28}

IMAGING

Ultrasonography and Endoscopic Ultrasonography

Ultrasonography (US) should be considered as an initial test in all patients with pancreatitis, especially if gallstones or biliary disease is suspected.²⁹ It can be done at the bedside with no sedation, making it an important tool in the evaluation of unstable patients. US is not currently used for grading the severity of pancreatitis or the extent of gland necrosis; however, contrast-enhanced US may change this situation. Contrast-enhanced US has a sensitivity and specificity of 82% and 89%, respectively.²⁹

Endoscopic ultrasonography (EUS) combines ultrasonography and endoscopic evaluation. It is less invasive than endoscopic retrograde cholangiopancreatography (ERCP) and has been shown to be clinically useful in diagnosing acute pancreatitis and choledocholithiasis. EUS may be useful when CT and US fail to show common bile duct stones. EUS may also be useful for selecting patients who might benefit from ERCP and early stone extraction. Petrov et al. reviewed studies of patients randomized to EUS-guided ERCP ($n = 213$) versus ERCP alone ($n = 210$). These authors showed that ERCP could be avoided in 67.1% of patients when EUS failed to identify gallstones.³⁰ The use of EUS significantly reduced the risk of overall complications (relative risk [RR] 0.35, 95% confidence interval [CI] 0.20-0.62) and post-ERCP pancreatitis (RR 0.21, 95% CI 0.06-0.83). One additional advantage of endoscopic ultrasonography is that it can be performed in pregnant women, patients with metallic implants, and patients who are too unstable to be transported out of the ICU.³⁰

Computed Tomography

Contrast-enhanced CT is considered the gold standard for diagnosing pancreatic necrosis and peripancreatic collections and for grading acute pancreatitis.^{22,23} Necrosis is detected by CT as focal or diffuse areas of diminished pancreatic parenchymal contrast enhancement (<50 Hounsfield units). The accuracy of this test is greater than 90%. CT findings of acute pancreatitis include interstitial edema, irregularity of the contour of the pancreas with obliteration of the peripancreatic fat planes, heterogeneous appearance with areas of decreased density within the pancreas, and variable ill-defined fluid collections (Fig. 98-2). The Balthazar index ranges from 0 to 10 and is obtained by adding the points attributed to the extent of the inflammatory process to the volume of pancreatic necrosis. Although CT findings correlate with clinical course and severity of disease in patients with acute pancreatitis, it is not necessary to obtain this study in patients with mild

FIGURE 98-2 ■ Computed tomography scan of a patient with severe necrotizing pancreatitis and Balthazar grade E scan; more than 50% necrosis of the gland was seen on previous scans of the gland, giving the patient a Balthazar index of 10.

pancreatitis. Obtaining an early CT scan may cause derangements of pancreatic microcirculation and may lead to contrast nephropathy. Therefore, CT scans before 72 hours of disease should be reserved for patients in which the diagnosis is in doubt.³¹

Endoscopic Retrograde Cholangiopancreatography

ERCP is an effective means of treating common bile duct stones.³² ERCP is not indicated for the management of mild pancreatitis or nonbiliary pancreatitis, and its overall use in patients with acute pancreatitis continues to be debated.³³⁻³⁵ Its main application is in the management of patients with biliary pancreatitis and biliary obstruction or cholangitis. There remains controversy regarding the role of ERCP for the management of patients with biliary pancreatitis but without bile duct obstruction.

Magnetic Resonance Cholangiopancreatography

Magnetic resonance imaging (MRI) and MRCP are noninvasive imaging modalities that are useful for depicting abnormalities of the pancreatic duct and parenchyma. MRI has several advantages over CT: there is no risk from radiation with MRI, it can detect pancreatic duct disruption, and it can help identify the etiology of acute pancreatitis. Without injection of gadolinium, MRI can discriminate between normal pancreatic parenchyma, the presence of edema, and the presence of necrosis, as well as differentiate between solid and liquid fluid collections. MRCP can be performed when ERCP has failed or is not possible, with the disadvantage that the former is just a diagnostic modality and further therapeutic interventions may need to follow.

While contrast-enhanced CT is considered the gold standard, a few studies suggest that MRI compares favorably with contrast-enhanced CT for the diagnosis and grading of severe acute pancreatitis. The major advantage of MRCP for SAP is that MRCP obviates the necessity for the infusion of iodinated contrast media and thereby may lower the risk of acute renal dysfunction in these critically ill patients.^{36,37} Bowel peristalsis, vascular motion artifacts, gastrointestinal air, and the presence of metallic clips can all degrade the quality of images obtained with MRCP. One disadvantage of MRI and MRCP is that acquisition of the image takes longer than with CT.

MANAGEMENT

General Support

Monitoring and Resuscitation

Several publications suggest that patients with SAP should be managed in an ICU, preferably by a specialist team. Resuscitation of intravascular volume is a key component of the initial management, regardless of the etiology and severity of acute pancreatitis. Sequestration of fluid into the extravascular extracellular compartment can lead to loss of as much as a third of plasma volume. Rapid restoration and maintenance of intravascular volume is essential because hypovolemia and shock are probably important factors contributing to the high incidence of acute renal failure among patients with SAP.^{9,16,38–40}

Aggressive fluid resuscitation has been shown to be important in the management of patients with acute pancreatitis, especially during the first 24 hours. Warndorf et al. conducted a retrospective study that associated early resuscitation (one-third of the total 72-hour fluid volume given within 24 hours) with a decrease in SIRS.³⁹ However, excessive inappropriate resuscitation can also lead to significant morbidity and mortality, including respiratory failure and abdominal compartment syndrome (ACS).^{3,40}

Single-organ or multiple-organ dysfunction is common, and monitoring of respiratory and cardiovascular status is essential. Adequate oxygen delivery to tissues and prevention of splanchnic ischemia are essential to prevent further organ injury. Vasoactive agents may be required, but they should be considered only after ensuring adequate resuscitation.

Even when systemic signs of adequate resuscitation are present, local inflammation in the pancreas can continue, leading to ongoing production of cytotoxic mediators. Treatment with protease inhibitors has been successful in experimental models of acute pancreatitis and is used via continuous arterial infusion in Japan.^{41–44} A trial was carried out comparing the administration of no infusions with continuous regional arterial infusions of the protease inhibitor, gabexate mesilate, plus antibiotics.^{43,45,46} Treatment with gabexate mesilate shortened the duration of abdominal pain and duration of SIRS, decreased the length of hospital stay, and decreased circulating levels of several markers of inflammation. Other studies have been unable to replicate these promising results. Yasunaga et al. found no significant differences in mortality (1% vs. 1.2%, $P = 0.789$) or median length of stay (10 days vs. 10 days, $P = 0.160$) between patients treated with and without gabexate mesilate.⁴⁵ A meta-analysis published in 2014 revealed no differences in mortality in patients treated with protease inhibitors when compared to those who did not receive protease inhibitors as part of their treatment.⁴¹

Although there has been significant interest in decreasing cytokine production by administering an anti-TNF antibody and IL-1 receptor antagonists, this approach has not been shown to be beneficial.^{5,47}

Pulmonary Dysfunction

Respiratory dysfunction is a major component of multiple-organ dysfunction syndrome secondary to acute pancreatitis. These patients may develop acute respiratory distress syndrome (ARDS) and require ventilator support. Although the mechanism by which pancreatitis leads to ARDS is not entirely clear, it is believed that pancreatic phospholipase A2 is released into the circulation and it degrades dipalmitoylcholine (a component of surfactant).^{7,48}

Pulmonary Management

Patients with SAP must be monitored closely for hypoxic and/or hypercarbic respiratory failure. Supplemental oxygen is almost uniformly required, and mechanical ventilation is often also required. Noninvasive positive-pressure ventilation (NIPPV) may be used to avoid endotracheal intubation in carefully selected patients. SAP is often associated with marked abdominal distention and diminished functional residual lung capacity on this basis. Management of acute lung injury and

ARDS secondary to SAP is similar to the management of these conditions associated with other primary problems (e.g., sepsis).⁴⁹

Pain Relief

Provision of pain relief to patients with SAP is not only humane but may also improve pulmonary dysfunction. In studies outside the United States, buprenorphine was noted to have a superior effect to procaine and did not exacerbate acute pancreatitis by promoting contraction of the sphincter of Oddi.⁵⁰ In a single trial comparing metamizole and morphine, no difference in analgesia was seen.⁵¹ Although IV narcotics are useful and effective, epidural analgesia with local anesthetics should also be considered.

Specific Support

Nutrition

Traditionally, patients with acute pancreatitis have been managed by providing IV fluids and nutrition, and avoiding enteral feeding to “rest” the inflamed pancreas and prevent stimulation of exocrine function and the release of proteolytic enzymes. Nevertheless, most patients with mild acute pancreatitis can begin oral supplementation within a few days of their presentation and do not require supplemental nutrition.

In the past, the primary approach for providing nutritional support for patients with SAP was total parenteral nutrition (TPN). TPN is expensive, may increase the risk of sepsis or metabolic derangements, and has been associated with alterations in gut barrier function.^{27,52,53} A meta-analysis of several trials of enteral versus parenteral nutrition for patients with SAP revealed that enteral nutrition reduced the frequency of infections, decreased the need for surgery, and shortened length of hospital stay.⁵⁴ Similarly, the Cochrane Group reviewed 8 trials of enteral versus parenteral nutrition and concluded that the relative risk (RR) of death with enteral nutrition was 0.50 (95% CI 0.28–0.91), RR for multiple-organ failure was 0.55 (95% CI 0.37–0.81), RR for systemic infection was 0.39 (95% CI 0.23–0.65), RR for operative interventions was 0.44 (95% CI 0.29–0.67), RR for local septic complications was 0.74 (95% CI 0.40–1.35), and RR for other local complications was 0.70 (95% CI 0.43–1.13). Mean length of hospital stay was reduced by 2.37 days (95% CI 7.18–2.44) in the enteral group.⁵²

If a nasoduodenal or nasojejunal tube is placed, care should be taken if blind manipulation through the duodenum is attempted as the duodenum is often distorted in patients with acute pancreatitis, and the risk of perforation is increased. In a meta-analysis of three randomized controlled trials by Chang et al., a comparison of nasogastric and nasojejunal feeding in patients with pancreatitis was performed. There were no differences in mortality (RR = 0.69, $P = 0.25$), tracheal aspiration (RR = 0.46, $P = 0.20$), diarrhea (RR = 1.43, $P = 0.43$), and exacerbation of pain (RR = 0.94, $P = 0.90$) between the two groups.⁵⁵ This suggests that nasogastric feeding was not inferior to nasojejunal feeding. Supplemental TPN may be valuable when nutritional requirements cannot be achieved using enteral nutrition alone or enteral access cannot be established. Ileus is not an absolute contraindication to enteral feeding, and most patients can tolerate continuous feeding at a slow rate.

Resting energy expenditure varies widely among patients with SAP, depending on the magnitude of the regional inflammatory process and the presence of additional complications, especially infection. Infection can increase energy expenditure by 5% to 20%, but overfeeding should be avoided, nutritional guidelines should be considered, and glucose control should be employed. Although triglyceride levels should be monitored and not be allowed to escalate to levels above normal, administration of lipids is safe and appropriate as there is no proven causal relationship between infusion of exogenous fat and the development of pancreatitis.

The timing of oral refeeding must be based on clinical judgment. Delayed nutrition is associated with increased frequency of infected necrosis/fluid collections, respiratory failure, and a need for ICU hospitalization.⁵⁶

PATHOGENESIS OF PANCREATIC INFECTION AND ANTIBIOTIC PROPHYLAXIS

Microorganisms can gain access to necrotic pancreatic and peripancreatic tissue via several routes, bacterial translocation from the colon being the most likely. Failure of the intestinal barrier permits bacteria and yeast to translocate from the lumen of the gut into ascites, mesenteric lymph, the bloodstream, and the pancreatic phlegmon. The notion that pancreatic infection in acute pancreatitis is due to infection by gut-derived organisms is supported by the observation that most pancreatic infections are monomicrobial and caused by gram-negative bacteria, at least when prophylactic antibiotics have not been administered.^{57–60} Further support for the intestinal origin of pancreatic infection in acute pancreatitis derives from data obtained in a clinical trial of selective decontamination of the gut, wherein enteral administration of poorly absorbed antimicrobial agents was associated with a significant reduction in late mortality, principally owing to decreased incidence of pancreatic gram-negative infection. Microorganisms can also gain access to pancreatic necrosis through hematogenous dissemination from infected central venous catheters, via the biliary tree, or via the pancreatic duct from the lumen of the duodenum.^{61,62}

The wisdom of using prophylactic antibiotics for managing acute pancreatitis has been debated for more than 50 years.^{58,60,63,64} When more than 30% of the gland is necrotic, pancreatic infection occurs in over 30% of patients with acute pancreatitis. Because approximately 80% of deaths due to acute pancreatitis are related to infectious complications, it is important to determine if administration of prophylactic antibiotics can decrease the incidence of local or distant infections or the morbidity and mortality associated with pancreatic necrosis.

There are three trials that are quoted to support the use of antibiotic prophylaxis for acute pancreatitis. The first trial by Pederzoli et al. randomized 74 patients to receive either imipenem or placebo. The secondary rate of pancreatic infection decreased from 30% in the control group to 12% in the imipenem group ($P = 0.10$). There were no beneficial effects on organ failure, mortality, or avoidance of surgery.⁵⁸ The second trial by Sainio et al. randomized 60 patients to receive either cefuroxime or placebo. The infectious complications and mortalities were more common in the group not treated with antibiotic prophylaxis compared with the group treated with cefuroxime (1.8 per patient vs. 1 per patient, $P = 0.10$; 7 vs. 1, $P = 0.03$, respectively).⁶³ Finally, the Luiten et al. trial randomized 102 patients to selective digestive decontamination versus standard therapy. There were 18 deaths among the 52 patients in the control group (35%) and 11 deaths among the 50 patients in the selective digestive decontamination group (22%; $P = 0.048$).⁶⁴

There are other trials that do not support the use of prophylactic antibiotics in the treatment of SAP. Isenmann et al.⁶⁵ compared ciprofloxacin and metronidazole to placebo while Dellinger et al.⁶⁶ did the same with meropenem and placebo. Both studies failed to show a difference in pancreatic infection and mortality rate.

Extrapancreatic infections appear to be lower in patients who receive prophylactic antibiotics. In a study by Hart et al. extrapancreatic infections were decreased when prophylaxis was used (RR 0.51, 95% CI 0.32–0.82).⁶⁷ Xu et al. also concluded that peripancreatic infection (RR 0.69, 95% CI 0.48–0.91) and extrapancreatic infection (RR 0.66, 95% CI 0.48–0.91) were reduced by administration of antibiotics.⁶⁸ In both these studies, there were no differences in mortality between treatment group and placebo group.

Instead of IV antibiotics, the use of probiotics has been considered. In a recent systematic review by Gou et al., 6 trials with a total of 536 patients were analyzed in order to determine if probiotic treatment was beneficial. Probiotics had no significant effect on total infections (RR = 1.09, $P = 0.57$), infection rate (RR = 1.19, $P = 0.47$), operation rate (RR = 1.42, $P = 0.71$), length of stay (RR = 2.45, $P = 0.35$), and mortality (RR = 0.72, $P = 0.25$).⁶⁹

Whether prophylactic antibiotics should be broadly applied for these indications is a controversial topic. One of the most concerning issues with respect to the routine use of prophylactic antibiotics is the change in microbial species over the past decade, with resistant bacterial species and fungal pathogens being commonly identified.^{4,57,70}

Fungal infection in SAP is a risk factor for morbidity and possible mortality. Prophylaxis with any broad-spectrum antibiotic may be associated with increased risk of infection with fungal species or resistant bacteria.⁷¹ If broad-spectrum bacterial agents are used, prophylactic use of an antifungal agent may be warranted. Although prophylactic antimicrobials administered IV or enterally are uniformly used in some institutions, the widespread use of prophylactic antimicrobials cannot be recommended without further data supporting the benefits of use over the apparent increase in antimicrobial resistance being reported in current series.

MANAGEMENT OF PANCREATIC NECROSIS AND ABSCESS

Pancreatic necrosis is defined by the presence of diffuse or focal areas of nonviable pancreatic parenchyma. It can be either sterile or infected. Pancreatic infection occurs in about 10% of all cases of acute pancreatitis but in 30% to 70% of cases with necrosis. Contrast-enhanced CT is currently the gold standard for documenting the presence of nonperfused pancreatic parenchyma. A pancreatic abscess is a circumscribed intraabdominal collection of pus, usually in close proximity to pancreatic necrosis, which arises as a consequence of acute pancreatitis.^{23,72}

Infected pancreatic necrosis should be suspected in patients with acute pancreatitis with clinical signs of sepsis, those who fail to improve with supportive therapy or regress after an initial period of improvement.^{73,74} Patients suspected of having infected pancreatic necrosis should undergo contrast-enhanced CT scan or ultrasound-guided fine-needle aspiration.^{75–77} This approach is a safe and reliable way to differentiate between sterile and infected necrosis. With Gram staining and culture of aspirated material, fine-needle aspiration by ultrasonography has a diagnostic sensitivity of 88% and specificity of 90%.⁷⁸ Because there is a possibility of contamination of sterile necrosis, fine-needle aspiration is indicated only in those patients with signs and symptoms of sepsis, those who fail to improve, and those who worsen after initial clinical improvement. It should not be performed as a matter of routine for patients with SAP who are doing well. Studies have confirmed infection rates of 2.8% to 22% in the first week and 28.8% to 55% in the second to fourth weeks. The timing of fine-needle aspiration should be based on the probability of infection, based on time of onset from the disease and the current clinical condition of the patient. Some authors do not support the practice of needle aspiration of infection because they use prophylactic antibiotics and would not perform an “early” operation based on cultures obtained from a fine-needle aspirate. Rather, they wait 3 to 4 weeks and, if the patient is unwell, operate at that time, whether or not the presence of infection has been proven.⁷⁹

Laboratory Markers of Infected Necrosis

No reliable blood test has been developed to establish the diagnosis of infected necrosis. CRP concentrations greater than 120 mg/L are associated with pancreatic necrosis.²⁵ There is no correlation, however, between the serum CRP level and the presence of infected necrosis. Procalcitonin is a 116-amino acid propeptide of calcitonin that has been shown to be a marker for severe bacterial and fungal infection. In the meta-analysis by Mofidi et al., the sensitivity and specificity of procalcitonin for predicting infected pancreatic necrosis were 0.80 and 0.91, respectively.^{26,73}

Clinicians must pursue the possibility of infected pancreatic necrosis in order to tailor the use of antibiotics and other forms of therapy. While fine-needle aspirates are an invasive modality and can be subject to sampling error, procalcitonin can be obtained noninvasively and is

not altered by antibiotic therapy. Importantly, the clinician must recognize that procalcitonin elevation is a nonspecific marker of potential infection, and if the procalcitonin level is elevated, a systematic search for all potential sites of infection should follow. However, the magnitude of procalcitonin elevation was found to be greatest in patients with intraabdominal infections as compared with respiratory or urinary tract processes.^{25,26}

Indication and Timing of Operative Intervention

Most experts now recommend delaying operation for pancreatic necrosis until infection has been identified.⁸⁰⁻⁸³ An intervention may be delayed until the third or fourth week of ICU care if the patient remains stable. In the past there was some belief that early surgery might improve outcome by removing necrotic tissue and decreasing the stimulus for systemic inflammation, but this notion has now been disproved.⁸⁴ Delaying as long as possible for any sort of invasive débridement has become the most common approach to managing patients with SAP and necrosis as early in the course of the disease, the pancreatic tissue is friable and nonviable tissues are not well demarcated. In addition, viable tissue is usually present, even when the gland grossly appears to be completely necrotic.

Nonoperative management of sterile necrosis is the standard of care according to several published guidelines. In selected cases, patients with extensive necrosis may not improve, and after a prolonged period of observation (6-8 weeks), operative débridement may be warranted.⁸⁴⁻⁸⁷

Operative Procedures

Although there is general agreement that infected necrosis requires drainage, there is no consensus about the best approach to achieve this goal.⁸⁸ All methods aim to remove infected tissue while preserving most of the gland. When a patient is very ill with sepsis, the primary treatment goal is to achieve drainage of infected material. Open necrosectomy has been associated with high rates of complications (34%-95%) and death (11%-39%).^{43,74,84,85,89} Although open treatment of infected pancreatic necrosis is still the most common procedure for débridement, fewer surgeons are using it as the initial treatment modality.

The "step-up approach" consists of percutaneous drainage followed by minimally invasive retroperitoneal necrosectomy, if needed. Patients who received the step-up approach were less likely to develop complications (40% vs. 69%, respectively).⁸³ Additionally, with the step-up approach, there was less organ failure (12% vs. 40%), lower rate of incisional hernia (7% vs. 24%), and lower incidence of new-onset diabetes mellitus (16% vs. 38%). This important trial is unique because it was a randomized study of the surgical care of infected necrosis rather than a case series reported from one or more institutions. The findings from this study also suggest that the step-up approach may be beneficial because of a lower level of surgical trauma and therefore activation of inflammatory mediators.^{74,83} Whether the step-up approach will fully replace open surgical débridement remains uncertain.⁴⁶

Percutaneous drainage of infected necrosis can be achieved in selected patients, especially when the infected material is not too viscous or too loaded with necrotic tissue. Drainage can be achieved via anterior or retroperitoneal approaches and is best achieved using a large-diameter catheter (12-14 F).⁸⁴

In recently reported studies, an endoscopic approach has been used to achieve drainage.^{78,90} Endoscopic ultrasound is used to identify collections through the wall of the stomach. Through serial dilations, the endoscope is advanced into the affected cavity; débridement is then performed with endoscopic instruments. A nasocystic drain is left in place for further irrigation and access.

The advent of minimally invasive techniques now allows for the use of several new approaches in drainage of infected pancreatic material such as video-assisted retroperitoneal drainage (VARD). Using laparoscopic techniques, the retroperitoneum is accessed and laparoscopic instruments are used for débridement of compromised tissue. In hospital, 30-day mortality for this procedure has been reported to be as

low as 2.5%, making it an attractive alternative.^{85,91} While VARD has the potential advantage of eliminating peritoneal contamination, many procedures are commonly needed, and the colon and other abdominal contents cannot be examined or treated if necessary.

Necrosectomy

Conventional resections have been abandoned in the treatment of SAP because of high complication and mortality rates. Necrosectomy removes devitalized tissue from the pancreas and surrounding retroperitoneum and can now be performed by open or less invasive endoscopic or laparoscopic techniques.^{80,90,92} Necrosectomy is designed to remove most of the devitalized tissue without injuring major blood vessels; hemostasis must be carefully obtained before the procedure is completed. Repeated drainage procedures may be necessary.

Additional abdominal complications in patients with acute pancreatitis include concurrent biliary tract problems, stress gastritis and related bleeding, necrosis of the transverse colon, hemorrhage from gastric varices secondary to splenic vein thrombosis, and catastrophic bleeding from ruptured pseudoaneurysms involving the gastroduodenal artery or branches of the superior mesenteric artery. Should massive gastrointestinal bleeding occur, and a gastric or proximal duodenal source is excluded, arteriography should be considered. Necrosis of the transverse colon should be considered in a patient with abdominal tenderness and distention and sepsis. Patients with colonic necrosis are usually dramatically ill. Enterocutaneous fistulas are commonly seen when the open packing technique is used and less commonly when other methods of management are employed.

OUTCOME

With an increasing number of patients surviving SAP, attention has been focused on the quality of life and long-term outcome of surviving patients. This patient population is subject to a wide range of medical problems, including diabetes mellitus, symptoms of polyneuropathy, recurrent pancreatitis, and continual abdominal pain, with endocrine or exocrine dysfunction occurring in the majority of patients.⁹³⁻⁹⁵ Major social problems can also be an issue, especially among patients with alcohol-induced pancreatitis. Chronic pancreatitis and related problems including pseudocysts, splenic vein thrombosis, and mesenteric pseudoaneurysms can occur.

In one study, 35 patients after acute pancreatitis treated with open necrosectomy were evaluated for results on the Short-Form 36 assessment of health-related quality of life. Among this cohort of 35 patients, 32 were employed at the time of their SAP, and 12 patients returned to work within 6 months of discharge. SF-36 scores were above 60% in all patients, and 20 of the 32 patients had a good quality of life (>70%).⁹⁴ Patients with alcoholic pancreatitis had the worst outcomes. In 20 survivors of long-term (>30 days) hospital stay after an episode of SAP, 12 out of 20 experienced morphologic or endocrine sequelae.⁹⁴ Problems noted more than 6 months after discharge from hospital included pancreatic fistulae, stenosis of both the pancreatic and biliary tree, and chronic abdominal pain.

SUMMARY

Acute pancreatitis is a widely variable disease that is usually mild in severity. SAP is a life-threatening disease, however, that can require intensive support, especially during the initial inflammatory period of SIRS, when massive fluid resuscitation and ventilatory, cardiovascular, renal, and nutritional support may be required. In patients with ongoing signs of SIRS beyond the second or third week of disease, progression from SAP with sterile necrosis to infected necrosis should be considered. Fine-needle aspiration should be employed to diagnose pancreatic infection. Débridement of infected pancreatic necrosis is required, but the exact method of surgical débridement is controversial, and a step-up approach to therapy may be best. Although SAP is a life-threatening disease, the overall survival of patients is about 90% at centers with expertise in the management of this complex syndrome.

KEY POINTS

1. Severe acute pancreatitis accounts for 10% to 15% of all patients presenting with pancreatitis and for virtually all the morbidity and mortality associated with the disease.
2. The early phase of severe acute pancreatitis is characterized by systemic inflammatory response syndrome and end organ dysfunction, often requiring intensive support of the cardiopulmonary system. Resuscitation of intravascular volume is an important component of initial management, regardless of the etiology and severity of acute pancreatitis. Sequestration of fluid can lead to loss of as much as one-third of plasma volume.
3. Infected pancreatic necrosis is the most important risk factor for death secondary to necrotizing pancreatitis. Prevention, diagnosis, and treatment of infection in severe acute pancreatitis are crucial.
4. Understanding the cause of severe acute pancreatitis may dictate therapeutic options. A biliary origin should be suspected in female patients older than 40 years of age with a serum alanine aminotransferase level more than three times the upper reference limit.
5. Contrast-enhanced computed tomography (CT) is considered the gold standard for diagnosing pancreatic necrosis and peripancreatic collections and for grading acute pancreatitis. The Balthazar index ranges from 0 to 10 and is calculated by adding the points attributed to the extent of the inflammatory process to the volume of pancreatic necrosis. Although CT findings correlate with clinical course and severity of acute pancreatitis, it is not necessary to obtain this study in patients with mild pancreatitis.
6. Approximately 80% of deaths due to acute pancreatitis are related to infectious complications. Although prophylactic administration of antibiotics is often employed, the quality of evidence supporting this practice is relatively weak. Moreover, problems associated with resistance to antibiotics have been observed in some recent clinical trials. Therefore, prophylactic antibiotics should not be used routinely.
7. Patients with severe necrotizing acute pancreatitis require nutritional supplementation. Enteral nutrition is safe and efficacious and may be best delivered distal to the pylorus. Some patients are so catabolic that enteral and parenteral nutrition may be required to support nutritional needs. Although triglyceride levels should be monitored, lipids can be used for supplementation in most patients.
8. Pancreatic infection should be suspected in three groups of patients: patients who fail to improve, patients who worsen, and patients with initial improvement who regress. A contrast-enhanced CT scan and fine-needle aspiration should be considered to rule out infection.
9. Pancreatic débridement and/or drainage should be performed in patients with infected pancreatic necrosis. The specific approach depends on local considerations, and no single method has been proven to be superior to another.
10. Increasingly, infected pancreatic necrosis is being managed using a more conservative staged or "step-up" approach and less invasive means of drainage in selected patients.

Critically ill patients with intraabdominal infection are at high risk for treatment failure and other serious complications. Failure can occur because of inadequate primary source control or the development of secondary complications such as abdominal compartment syndrome or fistula formation. Because there are few controlled studies of the management of patients with intraabdominal infection apart from trials of antibiotic therapy, and fewer still of critically ill patients with peritonitis, recommendations are often based on expert opinion, extrapolation from animal models, and sometimes on clinical data. Adequate and timely resuscitation is crucial for patients with intraabdominal infection to optimize tissue perfusion and oxygenation. Effective resuscitation can mitigate or avoid certain manifestations of intraabdominal infection in critical illness such as ischemic colitis or acute acalculous cholecystitis. Depending on the problem, source control can include drainage of intraabdominal abscesses, débridement of devitalized tissue, closure of perforations, reduction of the burden imposed by bacteria and their toxins, and the administration of appropriate and timely broad-spectrum antimicrobial therapy. Optimal management of these patients also requires understanding of peritoneal host defense, its limitations, relevant microbiology, and the factors that predict adverse outcomes.

■ PATHOGENESIS

Host Defenses

The peritoneal cavity is a complex space lined with mesothelial cells in the visceral and parietal layers. A healthy peritoneal cavity responds rapidly to bacterial contamination. Normally, about 50 to 100 mL of fluid circulates in the peritoneal cavity. The net fluid movement is cephalad toward the diaphragm, facilitated by normal peristalsis, spontaneous diaphragmatic excursions, splanchnic blood flow, and factors that maintain normal membrane permeability of the microcirculation. Conversely, ileus, mechanical ventilation, splanchnic hypoperfusion, and inflammation can disrupt normal fluid movement and cause intra-peritoneal fluid sequestration.

The major intraperitoneal host defense mechanisms include lymphatic clearance of bacteria, phagocytosis of bacteria by immune cells, and mechanical sequestration. Peritoneal macrophages and opsonic proteins circulate to facilitate phagocytosis. Small bacterial inocula in the peritoneal cavity are absorbed by specialized stomata on the undersurface of the diaphragm and are expunged into the thoracic lymphatic channels within a few minutes.¹ The bacteria then pass into the central venous system via diaphragmatic and mediastinal lymphatics, resulting in systemic immunogenicity. When an infectious inoculum is introduced, a brisk inflammatory response ensues to localize the infection, abetted by the omentum and other viscera nearby, leading to abscess formation rather than generalized peritonitis. Intraabdominal abscess formation is a source-containment process; mortality is about one-third lower for patients with abscess than for patients with generalized peritonitis.^{2,3}

Intraabdominal infection stimulates systemic inflammatory responses in addition to local phenomena. Locally, influx and activation of phagocytic cells mediate bacterial killing, impair microvascular integrity, and foster the generation of exudative ascites. Edema of the submesothelial interstitial space to a thickness of 1 mm sequesters

about 1.7 L of fluid in a 70-kg patient. Large volumes of interstitial and free peritoneal fluid can accumulate, resulting in hypovolemia. Whereas intraperitoneal fluid accumulation is detrimental to intraabdominal host defenses, diluting opsonins and impairing neutrophil function, intravenous (IV) fluid administration is imperative for the hypovolemic patient.

Macrophage- and monocyte-derived cytokines have been implicated in the pathophysiology of peritonitis. In gram-negative sepsis, the evident peritoneal tissue damage has been associated with excessive monocyte-derived cytokine release in response to endotoxins.^{4,6} In murine peritonitis model systems, sympathetic neurons regulate monocyte signaling, whereas cyclooxygenase inhibition may attenuate the deleterious effects of cytokines upon gut barrier function.^{7,8}

With inflammatory injury, peritoneal mesothelial cells are denuded, exposing the underlying basement membrane. When platelets and fibrin come into contact with the basement membrane, fibrin polymerization produces a typical exudative “rind” of fibrin and entrapped cells on peritoneal surfaces. Fibrin and apoptotic neutrophils contribute to the formation of adhesions and the walls of abscesses. Normally, the process is self-limiting by up-regulation or activation of fibrinolytic factors such as plasminogen within the first week after mesothelial injury. If the insult is self-limiting, peritoneal repair occurs within 3 to 5 days. Under local hypoxic conditions, the adhesions are invaded by fibroblasts, angiogenesis is stimulated, and the adhesions become tenacious.⁹

Microbiology

Most of the bacteria in the gut are commensal flora that play little if any role in the pathogenesis of intraabdominal infections. It is estimated that as many as 1000 bacterial species are present within the lumen of the healthy human colon. Most of these species are obligate anaerobes. Under normal conditions, the intestinal microbiota support enterocyte and colonocyte function and prevent the overgrowth of pathogenic species such as *Bacteroides fragilis*, *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp. Overgrowth of these potentially pathogenic microbes may occur after treatment with broad-spectrum antibiotics.

The bacterial density within the gut lumen increases along the length of the gastrointestinal tract from the stomach to the colon. When released from a gastrointestinal perforation, the bacteria must proliferate to cause infection, while local host defenses seek to prevent or contain the establishment of infection. Microbial colonization of peritoneal surfaces occurs rapidly after gut perforation due to microbial expression of specific adherence factors. Enterobacteriaceae predominate within the first 4 hours, and the *B. fragilis* group supersedes them within 8 hours. Adherent bacteria are difficult to eradicate by operative peritoneal lavage or mechanical means.¹⁰

Besides adherence factors, bacteria possess several other mechanisms for the expression of virulence. Peptidoglycans and lipoteichoic acid in the cell walls of gram-positive bacteria, especially streptococci and staphylococci, stimulate the host inflammatory response. These organisms can elaborate exotoxins and proteases that cause tissue injury and promote bacterial proliferation. Lipopolysaccharides in the outer cell wall of gram-negative bacteria can interact with many cell types to stimulate an inflammatory response. As bacteria proliferate

and the size of the inoculum increases, acidic bacterial metabolites can impair neutrophil function.¹¹ Larger inocula can render antibiotics such as β -lactams ineffective.¹² Some bacterial species alter their gene expression behaviors via extracellular signaling to maximize survival and proliferation, a phenomenon called the *quorum-sensing effect*,¹³ whereas others may express a virulent phenotype under conditions of metabolic stress.¹⁴

Synergistic interactions, usually among members of the *B. fragilis* group and either facultative gram-negative bacilli or enterococci, can suppress local host defenses and promote bacterial survival and growth.¹ *B. fragilis* produces a capsular polysaccharide antigen that suppresses complement activation and inhibits leukocyte recruitment and function.¹⁵ Anaerobic bacteria produce short-chain fatty acids that can impair the function of neutrophils, and they lower the redox potential of the microenvironment to favor proliferation. Facultative bacteria consume residual oxygen, permitting the survival and proliferation of obligate anaerobes. Aerobic and anaerobic bacteria can enhance the growth of other species by providing nutrients or by producing enzymes that inactivate antibiotics.

In some respects, bacteria have evolved the ability to take advantage of host defenses. As an example, bacterial adherence to colonocytes and bacterial growth are enhanced by physiologic concentrations of norepinephrine, whether secreted as part of the counterregulatory response to stress or exogenously administered.¹⁴

Peritonitis

Peritonitis is classified as primary, secondary, or tertiary. Most critically ill patients with intraabdominal infection have secondary or tertiary peritonitis. The bacterial sources characteristic of these classes of peritonitis are shown in Table 99-1.

Primary, formerly “spontaneous” bacterial peritonitis, develops in the absence of gastrointestinal perforation and rarely causes critical illness. This type of peritonitis, which afflicts adults with hepatic cirrhosis, patients with collagen vascular disease, or children with certain glomerulopathies, is almost always monomicrobial.¹⁶ The typical pathogen is usually an enteric gram-negative bacillus such as *E. coli* or *Klebsiella* spp., although streptococcal infections are also known to occur. Definitive diagnosis is made by paracentesis and fluid culture, and operative treatment is not indicated. The presence of polymicrobial or anaerobic flora confirms a visceral perforation that must be treated, usually with surgical exploration.

Device-associated peritonitis is a variant of primary peritonitis that is also almost always monomicrobial. The majority of cases occur with chronic ambulatory peritoneal dialysis (CAPD) catheters, among which the incidence of peritonitis approaches one episode per year of dialysis.¹⁷ The most common pathogens are *Staphylococcus aureus*, *Pseudomonas* spp. and *Candida* spp. Although rare, recurrent CAPD-related peritonitis due to methicillin-resistant *S. aureus* (MRSA)

has been associated with the emergence of vancomycin-resistant strains after treatment with multiple courses of vancomycin.¹⁸ Recent studies have suggested that the administration of periprocedural IV antibiotics and modern device connection techniques reduce the risk of developing device-associated peritonitis.¹⁹ Treatment consists of prompt catheter removal. A 2014 Cochrane review demonstrated that intraperitoneal glycopeptide antibiotic administration is superior to IV antibiotics for achieving resolution when the pathogen is a gram-positive coccus.²⁰

Secondary peritonitis follows perforation of a hollow gastrointestinal viscus. The majority are community-acquired cases. Appendicitis is the most common cause, and the polymicrobial bacterial flora are typically highly susceptible to antibiotics in North America and Europe, although less so in the developing world. Thorough microbiologic analysis of a carefully collected specimen of purulent peritoneal fluid from a patient with secondary peritonitis yields an average of 5 organisms. *B. fragilis* is the most commonly isolated obligate anaerobe, and *E. coli* is the most commonly isolated facultative organism. Less common isolates include *Enterococcus* spp., *Candida* spp., *Clostridium* spp., and *Pseudomonas aeruginosa*. These uncommon isolates do not need antibiotic therapy if the patient was previously healthy, does not have comorbid conditions that increase the risk of an adverse outcome, and has a community-onset infection.

Timely, effective operative source control, combined with a short course of broad-spectrum antibiotics, is curative in more than 85% of all cases and more than 90% of appendicitis cases.²¹ Laparoscopic peritoneal lavage may offer an alternative treatment for select cases of secondary peritonitis. A recent review demonstrated a mortality rate of 1.7% and success rate of 96% among 231 patients with perforated diverticulitis (mostly Hinchey grade 3) managed primarily with laparoscopic peritoneal lavage,²² but multicenter trials are needed. Most cases of community-acquired peritonitis do not result in severe illness, and they seldom require intensive care, but when they do, the mortality rate can exceed 25%.

Tertiary peritonitis describes recurrent or persistent intraabdominal infection after failure of more than one source control procedure to control the infection.²³⁻²⁵ The flora usually include one or more strains of staphylococci (often MRSA) and *Enterococcus* spp., *Candida* spp., or *Pseudomonas* spp.²⁶⁻²⁸ It is debatable whether tertiary peritonitis represents invasive infection or colonization of the peritoneal cavity in the face of impaired host defenses. Fluid collection is often poorly localized and serosanguineous rather than purulent, suggesting an element of host defense impairment. Cases of tertiary peritonitis are fortunately uncommon, but level I evidence for specific management strategies is lacking.

Adjuvants

Adjuvant substances act to decrease the threshold bacterial inoculum necessary to result in infection. Adjuvants can increase virulence or interfere with host defenses, and they are invariably present in patients with gastrointestinal perforation. Common adjuvants include ascites, blood, fibrin, bile, urine, chyle, pancreatic fluid, and platelets.²⁹ Foreign bodies (e.g., nonabsorbable mesh or sutures) may also act as adjuvants. The principal adjuvant is blood. Hemoglobin, fibrin, and platelets all impair host defenses, and iron is essential for bacterial growth and depresses phagocyte function. Fibrin promotes bacterial trapping and abscess formation and can sequester bacteria from neutrophils. Bile salts impair host defenses and are toxic to neutrophils.³⁰ Further, pancreatic enzymes may be activated by bacteria, producing necrotic tissue that may become infected.

Foreign materials, when acting as adjuvants, serve as the foci of bacterial adherence and sequestration from phagocytes. Foreign material may also elicit inflammation, thereby reducing the minimal inoculum necessary to generate infection. Adjuvant foreign materials include surgical drains, nonabsorbable suture material, fibers from gauze sponges, prostheses such as vascular grafts and mesh, topical hemostatic agents, talc, barium sulfate, necrotic tissue, and feces.

Barium produces a marked chemical peritonitis and activates coagulation via the intrinsic pathway; the combination of barium and feces can be lethal.

THE AT-RISK PATIENT

Fortunately, most patients with intraabdominal infection do not require care in an intensive care unit (ICU). In a population-based study of hospital discharges for peritonitis, severe sepsis developed in only 11% of cases (Table 99-2) but increased the mortality risk by 19-fold.² Similarly, only about 15% of patients enrolled in clinical trials of antimicrobial therapy for secondary peritonitis have an Acute Physiology and Chronic Health Evaluation (APACHE) II score above 15 points.³¹

Some patients with community-acquired secondary peritonitis develop critical illness due to delayed presentation, immunosuppression, or extremes of age. Most patients with peritonitis suffer critical illness due to a hospital-acquired source (Table 99-3). The leading causes of hospital-acquired peritonitis are gastrointestinal anastomotic dehiscence and splanchnic ischemia due to hypovolemia, distributive shock, atheroembolism, and thromboembolism. Hospital-acquired peritonitis is usually polymicrobial; organisms isolated commonly include *Enterococcus* spp., *Candida* spp., *P. aeruginosa*, and other antibiotic-resistant organisms such as MRSA.^{23,27,28}

Surgical ICUs that care for patients with multiple trauma or following emergency surgery are likely to have more cases of intraabdominal infection than medical ICUs. Surgical patients that require operation for source control or have a postoperative secondary nosocomial infection account for 25% to 40% of patients with severe sepsis. Units with a low prevalence of postoperative secondary peritonitis must be equally vigilant in their surveillance and assessment, because a missed intraabdominal infection is frequently fatal.³²

| TABLE 99-2 Risk Factors for Severe Sepsis in Patients With Intraabdominal Infections | | |
|--|---------------|--------------------------|
| PARAMETER | RELATIVE RISK | 95% CONFIDENCE INTERVALS |
| AGE (YEARS) | | |

| Renal dysfunction | 2.0 | 1.4-2.9 |

Data from Anaya and Nathens.²

When patients with intraabdominal infection are critically ill, mortality exceeds 25%. The risk of failure increases with the severity of the illness, inadequate empiric antibiotic therapy, delayed surgical therapy, and failure of source control.^{23,27} Most clinical failures are not associated with multidrug-resistant pathogens; however, some studies have suggested that resistant pathogens cause clinical failure in some cases of postoperative peritonitis.^{33,34}

SPECTRUM OF DISEASE CAUSING CRITICAL ILLNESS

Abscess of Solid Organs

Although abscesses of solid organs are rare, failure to diagnose them properly may result in death. Most cases arise as a complication of a community-acquired infection, but on occasion, they can result from complications of medical care. The liver is affected most commonly, followed by the spleen and the kidney.

Pyogenic liver abscess is most often the result of ascending biliary infection (cholangitis) or portal bacteremia that complicates an enteric infection (typically colonic diverticulitis). The most common causative organisms include *Klebsiella* spp., *E. coli*, and *Enterococcus* spp. *K. pneumoniae* has surpassed *E. coli* as the most common bacterial isolate in pyogenic liver abscess.³⁵ Systemic bacteremia may also cause liver abscesses and may entail dental abscess (viridans streptococci) or vascular catheters (*S. aureus*, *C. albicans*, and others). Devitalized liver from trauma, angioembolization, and ablation of neoplasms are at particular risk of infection.

Antibiotic therapy for liver abscesses is obligatory and should be tailored to the source of origin. A treatment course of more than 14 days may be necessary. Amebic liver abscesses are treated primarily with metronidazole. A recent Cochrane review determined the quality of the literature as being insufficient to conclude whether percutaneous aspiration improves outcomes for amebic abscesses.³⁶ Among pyogenic liver abscesses, if the size and location of the abscess permit, percutaneous drainage should be attempted.^{35,37,38} Operative drainage may be required for abscesses that cannot be drained percutaneously. A 2013 study of 85 patients with pyogenic liver abscesses found treatment failure in 40% of patients who underwent percutaneous drainage, compared with 11% who underwent laparoscopic drainage procedures.³⁹ Recently, endoscopic ultrasound-guided liver abscess drainage has

been described and may represent an alternative route of access to drain pyogenic liver abscesses.⁴⁰ Overall mortality rates for liver abscesses approach 25% and are higher for patients with multiple abscesses that are too small to drain (i.e., miliary abscesses).⁴¹

Splenic abscesses are uncommon and usually result from hematogenous or local contamination. Hematologic sources include endocarditis, urinary tract infection, pneumonia, osteomyelitis, otitis, mastoiditis, and pelvic infection. Systemic disorders such as hemoglobinopathies or sickle cell disease can cause splenic infarction. Devitalized splenic tissue resulting from trauma, infarction, or embolization can become infected and produce a splenic abscess.⁴² Splenic abscesses have been reported with other systemic infections, including typhoid fever, paratyphoid fever, malaria, and candidiasis. Additionally, adjacent infections of the pancreas, retroperitoneum, subdiaphragmatic spaces, and diverticulitis may extend directly into the splenic parenchyma.

S. aureus is the most common pathogen in splenic abscesses, whereas gram-negative organisms are relatively unusual. Anaerobic infections (e.g., *Clostridium perfringens*) have also been described. Empiric antibiotic therapy should address all likely pathogens. Percutaneous drainage can be attempted if conditions are favorable, but splenectomy and drainage usually comprise definitive therapy. The overall rate of mortality for splenic abscess is approximately 20%.

Despite the frequency of “urosepsis,” true abscesses of the kidney are uncommon as compared with hepatic or splenic abscesses. Ascending infection from the lower urinary tract is the usual source; therefore, any common urinary tract pathogen (*E. coli*, *Klebsiella* spp., *Enterococcus* spp., *S. aureus*) can be causative. Initial treatment should thus include broad-spectrum antibiotics until microbiologic speciation and susceptibility profiles become available. Surgical drainage may be required for patients with recurrent sepsis, or for those who do not respond to antibiotic therapy.

Acute Acalculous Cholecystitis

In contrast to gallstone-related cholecystitis, the etiology of acute acalculous cholecystitis is gallbladder ischemia with secondary infection of the organ.⁴³ Acute acalculous cholecystitis may complicate several conditions that produce splanchnic hypoperfusion. Risk factors in medical patients include congestive heart failure, diabetes mellitus, abdominal vasculitis, and malignant disease (including after bone marrow transplantation). Acalculous cholecystitis is more common in surgical patients and can occur following burns, trauma, cardiopulmonary bypass, biliary instrumentation, and emergency aortic surgery.⁴³

The diagnosis of acute acalculous cholecystitis can be challenging, and a high index of suspicion is required. Prompt diagnosis and therapy are necessary, as necrosis of the gallbladder occurs in 30% of patients, and gallbladder perforation occurs in 4%. Fever and hyperbilirubinemia are common associated findings.⁴⁴ Serum transaminase and alkaline phosphatase concentrations may also be elevated. When signs and symptoms can be localized to the right upper quadrant, the differential diagnosis includes gastroduodenal perforation, acute pancreatitis, right colon ischemia, and acute hepatitis.

Gallbladder wall thickness greater than 3.5 mm and the presence of pericholecystic fluid by bedside ultrasonography are sufficient to diagnose acute acalculous cholecystitis. Computed tomography (CT) is equally accurate and can be utilized when physical examination findings are equivocal and the patient is stable for transport. Hepatobiliary scintigraphy (HIDA) has a poor positive predictive value for acalculous cholecystitis, as patients generally do not receive sufficient alimentary stimuli for gallbladder contraction. Administration of morphine sulfate, which increases biliary hydrostatic pressure, can promote the filling of the gallbladder and increase the diagnostic accuracy of hepatobiliary scintigraphy.⁴⁵

Percutaneous cholecystostomy is the treatment of choice for acute acalculous cholecystitis in the critically ill patient. Success rates exceed 90% for the control of acute acalculous cholecystitis, although the

overall mortality rate remains about 30%. Percutaneous cholecystostomy fails most commonly due to malposition of the drainage catheter, uncontrolled gallbladder perforation, or another diagnosis. If a cholecystostomy tube study confirms the absence of gallstones once the patient has recovered, the drain can be removed. Interval cholecystectomy is unnecessary if the drain is removable.

Ischemic Colitis and Enteritis

Intestinal ischemia is a dangerous and relatively common complication of critical illness that can progress within hours to gangrene, perforation, and generalized peritonitis.⁴⁶ The splanchnic circulation is especially vulnerable to low cardiac output, particularly when the cardiac index is less than 2 L/min/m². Most cases are caused by nonocclusive ischemia, often a sequela of hypovolemia, shock, and the administration of vasopressors. A number of other causes have been identified. Acquired deficiencies of protein C or S are characterized by hypercoagulability that has been associated with mesenteric arterial and venous thrombosis. Chronic atrial fibrillation or dilated cardiomyopathy can lead to mesenteric arterial thromboembolism. Arteriography may result in cholesterol embolization from dislodgment of atherosclerotic plaques. Intestinal ischemia must also be considered in patients with partial or proximal bowel obstructions, as manifestations may not be obvious under these conditions.

The pattern of injury with intestinal ischemia varies with the mechanism, the presence of heart disease, and the status of the collateral circulation via the celiac and inferior mesenteric arteries. Large thrombi usually occlude the superior mesenteric artery at a narrow point just distal to the origin of the middle colic artery. The first 30 to 45 cm of the small bowel and the left colon may be spared. Smaller emboli may result in patchy intestinal necrosis and are more likely to affect the small bowel and ascending colon (Fig. 99-1). Nonocclusive ischemia classically occurs in watershed areas of the mesenteric circulation where collateral vessels bridge two arterial distributions. Although any segment of intestine can be affected by nonocclusive ischemia, the cecum (farthest from the inferior mesenteric artery collaterals) and the splenic flexure (watershed of the superior and inferior

FIGURE 99-1 ■ Computed tomography after the administration of oral and intravenous contrast in a patient with embolic occlusion of the superior mesenteric artery and patchy ischemia of the small bowel and right colon (arrows). Bowel ischemia is evident from the marked thickening of the intestinal wall.

FIGURE 99-2 ■ Computed tomography with oral and intravenous contrast in a patient with nonocclusive mesenteric ischemia of the colon at the splenic flexure (arrow). Ischemia of the colon is evident from the marked thickening of the colon wall.

mesenteric arteries) are most likely to be affected (Fig. 99-2). The left colon is particularly vulnerable after abdominal aortic operations, especially when the inferior mesenteric artery has been ligated during the procedure.

Patients with acute intestinal ischemia are often profoundly ill and will die without prompt intervention. As the blood supply to the mucosa is more vulnerable than to the seromuscular layers, transmural necrosis represents late-stage disease. Patients can develop severe sepsis or septic shock before transmural gangrene or perforation. The diagnosis is often challenging due to the protean manifestations of the syndrome and potential for ischemia at any point of the gastrointestinal tract from the ligament of Treitz to the mid-rectum.

Among communicative patients, severe pain that is disproportionate to tenderness by palpation is the diagnostic hallmark. Among intubated, sedated patients, the clinical features can be subtle. Abdominal distention, hypovolemia, hemoconcentration, unexplained and refractory metabolic acidosis, or occult rectal bleeding may be among the only signs. Hematochezia following abdominal aortic surgery or resuscitation from shock is strongly suggestive of colon ischemia.

Given the propensity for left colon involvement, lower endoscopy at the bedside is usually the first diagnostic modality, but a number of pitfalls should be recognized. Flexible sigmoidoscopy is simple and safe but may miss ischemia at or proximal to the splenic flexure; accordingly, colonoscopy is preferred (Fig. 99-3). Endoscopy visualizes only the mucosa and can underestimate the extent of the disease. CT and CT angiography are increasingly useful diagnostically and have largely supplanted the use of formal arteriography (Fig. 99-4).

Bedside diagnostic laparoscopy represents a technique that can be used to identify intraabdominal pathology in the ICU setting, but reports to date are anecdotal. Laparoscopy should be considered when transferring the patient to radiology or the operating room is considered unsafe or when routine radiologic examinations are inconclusive.^{47,48} Diagnostic testing should be foregone entirely in favor of immediate laparotomy if signs of peritonitis are present.

Surgical therapy is individualized based on the location and extent of the intestinal compromise and the physiologic state of the patient. Infarcted bowels are resected, but bowels of questionable viability may be left for re-inspection at a second-look laparotomy 12 to 48 hours later, particularly if a massive enterectomy would otherwise be needed.

FIGURE 99-3 ■ Colonoscopy is the preferred modality to assess for colonic ischemia but visualizes the mucosa only and may underestimate the extent of the disease.

FIGURE 99-4 ■ Computed tomography after administration of oral and intravenous contrast in a patient with an embolism to the superior mesenteric artery and ischemia of the small bowel and right colon. The arrow points to the embolus in the superior mesenteric artery.

Anastomosis can be performed in stable patients without peritonitis or deferred in unstable patients by leaving the occluded ends of the bowel in temporary discontinuity until the second-look procedure. Creation of a temporary ostomy is a third option, although this is performed with decreasing frequency. If a second-look procedure is unnecessary, the abdominal fascia can be closed. If reoperation is planned or if bowel edema and distention are such that definitive closure would risk the development of intraabdominal hypertension or abdominal compartment syndrome, damage-control principles are utilized, and a temporary abdominal wall closure is performed. Methods for temporary closure include closure of the skin only or closure with absorbable mesh, biologic material, or plastic sheeting, usually in conjunction with a negative-pressure wound therapy system.⁴⁹ Expert reviews of surgical literature have concluded that negative-pressure wound therapy systems achieve superior outcomes when compared with alternative temporary closure techniques.⁵⁰⁻⁵²

The wide spectrum of disease in patients with intestinal ischemia makes mortality estimates difficult, but the condition is highly morbid. Acute colon ischemia following repair of a ruptured abdominal aortic aneurysm has a mortality risk as high as 80%.

Clostridium difficile Colitis

The incidence and severity of *C. difficile* infections (CDI) are increasing. CDI remains the most common nosocomial gastrointestinal infection, and it carries substantial morbidity and mortality. Early diagnosis and treatment are essential for a favorable outcome. A highly virulent strain, PCR ribotype 027, has been associated with recent outbreaks in North America and Europe. It is characterized by depressed toxin production and a higher risk of mortality relative to other strains.⁵³ Patients in the ICU are at increased risk for CDI, and in these patients, the disease is more frequent, more severe, more refractory to medical therapy, and subject to higher rates of relapse.⁵⁴ In one study, among patients with CDI requiring ICU admission, emergency total abdominal colectomy was needed in 25%. Diverting loop ileostomy, intraoperative colonic lavage, and postoperative enterostomal vancomycin administration allow successful preservation of the colon in up to 93% of patients with severe complicated CDI in the absence of necrosis or perforation.⁵⁵ Other risk factors for CDI include preoperative antibiotic use, uremia, burns, chronic obstructive pulmonary disease, cancer, abdominal surgery, cesarean section, antiperistaltic medications, proton-pump inhibitors, ICU stay, prolonged hospital stay, chemotherapy, and postpyloric tube feeding.^{53,54}

Clinical examination of patients with CDI may not reveal notable findings of peritonitis unless megacolon or perforation has developed. CT can demonstrate typical findings of colonic wall thickening, dilation, and the so-called *accordion sign* (thickened haustral folds and trapped contrast material, ascites, or pericolic stranding; Fig. 99-5). Identification of the organism by polymerase chain reaction detection of bacterial DNA and endoscopy are useful diagnostic adjuncts, but definitive management in patients with evidence of refractory fulminant colitis should not be delayed for these tests. Routine cases of CDI are treated with oral or IV metronidazole. Severe disease is treated with oral vancomycin, which achieves high intraluminal concentrations owing to the lack of absorption across the gut mucosa.

Fulminant CDI with perforation, toxic megacolon, severe ileus, hypotension, or refractory sepsis occurs in approximately 3% to 8% of

patients. Patients who have a history of inflammatory bowel disease, recent surgery, prior treatment with IV immunoglobulin (Ig) or a vasopressor, leukocytosis, or increased blood lactate concentration should have early surgical consultation. Mortality is notably decreased in patients who have no more than 6 days of medical treatment prior to operation, which supports early total abdominal colectomy for appropriate patients.⁵³⁻⁵⁷

Acute Pancreatitis

Gallstone disease and alcohol consumption account for about 80% of cases of pancreatitis. Trauma, upper abdominal surgery, and cardiopulmonary bypass account for the remainder. Approximately 85% of cases are self-limiting and have a good prognosis. The remaining 15% of cases account for most of the morbidity and all of the mortality. Infection is the most common complication and can lead to multiple organ dysfunction syndrome and death. Mortality risk is associated with large IV fluid requirement, acidosis, and hypocalcemia.⁵⁸ Antibiotic prophylaxis is ineffective and not recommended.

Pancreatic infections include infected pseudocysts, discrete pancreatic abscesses, or infected pancreatic necrosis. The last is a poorly localized process that affects the retroperitoneal fat as well as the pancreas itself. Infection can develop as early as 5 days after the onset of acute pancreatitis, with the peak incidence at day 14. Almost any common organism can cause infection, including staphylococci, enteric gram-negative bacilli, obligate anaerobes, *P. aeruginosa*, and *Candida* spp. Assuming appropriate microbial susceptibility, imipenem-cilastatin, meropenem, doripenem, or a fluoroquinolone plus metronidazole are recommended empiric antimicrobial agents.⁵⁹ Kinetic studies of drug accumulation in normal pancreas or pancreatic fluid suggest adequate pancreatic concentrations are achieved by fluoroquinolones, carbapenems, metronidazole, and fluconazole, whereas aminoglycosides are ineffective.⁶⁰

Many aspects of the prevention and management of pancreatic infection are controversial, including the role of antibiotic prophylaxis, diagnostic methods, and techniques and the timing of the surgical drainage and debridement. Antibiotic prophylaxis of severe pancreatitis with imipenem-cilastatin or meropenem is ineffective and has been associated with an increased risk of fungal infection.⁶¹ Regardless of the severity of the illness, all patients with pancreatitis should undergo ultrasonography to evaluate for gallstones. Pancreatic protocol CT is the best study to define anatomic severity and infection. The study should be performed with contrast infusion and thin (1-mm) cuts through the region of the pancreas to assess for viability and the presence of devitalized tissues (Fig. 99-6). When peripancreatic infection is suspected, CT-guided aspiration should be performed to obtain material for culture.

Source control is essential for patients with established pancreatic infection. Newer techniques with acceptable outcomes and lower morbidity have begun to replace traditional open drainage and surgical necrosectomy. These techniques include minimally invasive endoscopic, radiologic, and laparoscopic approaches. Endoscopic ultrasonography as a guide to drainage and laparoscopic pancreatic necrosectomy has demonstrated success in managing pancreatic necrosis (Fig. 99-7).^{62,63} The results from the Dutch Pancreatitis Study Group demonstrated a significant reduction in major complications (new-onset multiple organ dysfunction syndrome, incisional hernias, and new-onset diabetes mellitus) following a “step-up” approach for managing infected pancreatic necrosis. This approach consists of percutaneous drainage, followed by minimally invasive retroperitoneal necrosectomy, if necessary.⁶⁴ Improvements in resuscitation and operative management of the infectious complications of pancreatitis have reduced the mortality rate to about 20%, about one-half that of the previous era.

Operation for patients with pancreatic necrosis and organ dysfunction without infection is a matter of debate. Current opinion favors a conservative approach with aggressive critical care support, reserving operation for confirmed walled-off infections.⁶⁵ This strategy is meant

FIGURE 99-5 ■ Computed tomography with oral and intravenous contrast in a patient with *Clostridium difficile* colitis. Typical findings include colonic wall thickening (arrows), dilation, and accordion sign (thickened haustral fold and trapped contrast material, ascites, and pericolic stranding).

FIGURE 99-6 ■ Computed tomography with oral and intravenous contrast in a patient with severe acute pancreatitis. The borders of the pancreas are indistinct from the surrounding marked inflammation. The hypodense area in the body of the pancreas is an area of pancreatic necrosis (arrow). Study should be performed with contrast infusion and thin cuts through the region of the pancreas.

FIGURE 99-7 ■ Interval computed tomography in the same patient as in Fig. 99-6, with pancreatic necrosis and pseudocyst formation. Significant resolution was observed after internal endoscopic drainage, with two stents functioning as a cystogastrostomy (arrow).

to minimize the complications associated with difficult and potentially morbid procedures, including hemorrhage, intestinal fistulas, multiple reoperations, open abdomen management, and abdominal wall hernias.

■ DIAGNOSIS

Diagnosis of intraabdominal infection in critically ill patients can be challenging. Medical history is often unobtainable, and altered mental status can mask the physical findings. At times, the only clue may be unexplained signs of sepsis or organ dysfunction. Radiologic testing is diagnostic in most patients.

Although good-quality plain abdominal radiographs are difficult to obtain at the bedside, pneumoperitoneum (Fig. 99-8), intestinal obstruction, or signs of intestinal ischemia may be found.

FIGURE 99-8 ■ Pneumoperitoneum (crescent-shaped lucency) is evident under the right hemidiaphragm on an upright chest radiograph of a patient with perforated sigmoid diverticulitis. The crescent-shaped lucency under the left hemidiaphragm is a stomach bubble.

Pneumoperitoneum can be an innocuous finding in mechanically ventilated patients and for as long as 7 days after open abdominal operations.^{66,67} Plain radiography can be augmented by water-soluble contrast injection of drains, fistulas, or sinuses to define the anatomy of complex infections or monitor resolution after drainage. Ultrasonography can be performed at the bedside and provides excellent visualization of the biliary tree.

Ultrasonography can also detect abscesses, particularly in the pelvis when transvaginal or transrectal probes are used and can be used to guide percutaneous drainage procedures. Visceral blood flow is assessed with the addition of color Doppler flow analysis. Unfortunately, ultrasonography is operator dependent. Visualization is limited in the presence of bowel gas, and dressings, stomas, and drains can impede the positioning of the probe.

CT with oral and IV contrast is the primary radiologic imaging study for the abdomen and pelvis.⁶⁸⁻⁷⁰ CT signs of intraabdominal infection include extraluminal gas (Fig. 99-9), free fluid, contrast extravasation, fat stranding, and the presence of a contrast-enhancing rim that is characteristic of abscess (Fig. 99-10). CT is now the test of choice for the diagnosis of intestinal obstruction. Intramural gas may be identified when mesenteric ischemia is present; occasionally, a thrombus is seen in a visceral vessel (Fig. 99-4). In the absence of generalized peritonitis or disruption of visceral structures, CT-guided percutaneous drainage is the treatment of choice for abscesses and intraabdominal fluid collections.^{37,38,70}

Although CT is an excellent diagnostic modality, obtaining an adequate study in critically ill patients can be problematic. When patients are unstable hemodynamically or dependent on a high level of mechanical ventilator support, transport out of the ICU may be risky.⁷¹ Iodinated contrast agents may precipitate acute kidney injury or aggravate chronic kidney disease. If the need for CT is anticipated 24 hours in advance, hydration and sodium loading may limit the risk of contrast-induced nephropathy.⁷²

Other radiologic modalities used commonly in elective evaluations have limited value in critical illness. Radionuclide imaging and magnetic resonance are used rarely for ICU patients with intraabdominal infection.

FIGURE 99-9 ■ Computed tomography with oral and intravenous contrast in a patient with pneumoperitoneum from a perforated viscus. Multiple pockets of extraluminal gas are evident (arrow), particularly anterior to the loops of the small bowel.

FIGURE 99-10 ■ Computed tomography with oral and intravenous contrast material in a patient with a large pelvic abscess. The abscess cavity demonstrates classic rim enhancement of the abscess wall (arrow). Percutaneous drainage should be performed under image guidance.

■ PRINCIPLES OF MANAGEMENT

Source Control

Source control for complicated intraabdominal infections remains the most important component of successful treatment. Consensus guidelines aim to implement source control interventions within the first 6 hours of management.^{73,74}

The elements of definitive source control include the removal of infected or nonviable material, closure or control of perforations, and the reduction of peritoneal contamination by bacteria and toxins. Multiple staged operative procedures may be needed. Failure to obtain adequate source control reportedly occurs in 10% to 25% of cases of intraabdominal infection, depending on the severity and complexity of the infection.^{23,74}

Abscess

Abscesses are characterized by local acidosis, low oxygen tension, poor antibiotic penetration, and impaired leukocyte function. Studies

of diverticular disease have reported that abscesses smaller than 3 cm in diameter are likely to resolve with antibiotics alone.⁷⁵ Source control with percutaneous drainage is the treatment of choice for most abscesses, provided adequate drainage is possible and no débridement or repair of anatomic structures is necessary.^{18,73} Percutaneous decompression of abscesses is successful and results in rapid clinical improvement in 85% of cases.^{37,38} Formal operative intervention should be performed without delay if clinical improvement does not occur promptly following drainage.

Peritoneal Toilet

Once source control has been achieved, additional intraoperative measures, including irrigation with fluid or antibiotic solutions and débridement of peritoneal surfaces, are ineffective and may be deleterious.⁷⁶⁻⁷⁸ Bacteria adhere to mesothelial cells on the serosal surfaces in peritonitis, rendering them resistant to removal by passive irrigation.⁷⁸⁻⁸⁰ A prospective trial demonstrated identical rates of intraabdominal abscess among 220 patients treated with suction alone or peritoneal irrigation and suction during appendectomy for perforated appendicitis (18.3% vs. 19.1%; $P = 1.0$).⁸¹ Moreover, animal studies suggest that irrigation fluids disseminate infection by hindering the normal immunologic function of the peritoneum. It has been shown that irrigation with antibiotic solutions confers no benefit if parenteral antibiotics are administered⁹; however, a meta-analysis has also shown that pooled mortality is three-fold higher when saline solution is used rather than antibiotic solution for peritoneal lavage.⁷⁶ High-volume lavage and pulse irrigation used in feculent or purulent peritonitis may be of benefit but may also increase the risk of fistula formation.⁷⁸⁻⁸⁰ Closed suction drains do not prevent recurrent fluid collections and are ineffective at draining the peritoneal cavity.

The Open Abdomen

Open abdomen management techniques are employed in select patients with diffuse peritonitis, inadequate primary source control, intestinal ischemia and discontinuity, abdominal compartment syndrome, or necrotizing infections of the anterior abdominal wall.^{82,83} Open abdomen is a component of the damage-control tactics used in unstable patients with massive trauma. In cases of peritonitis, goals of damage control include the assessment and reassessment of intestinal viability, decompression of the abdomen, and access for peritoneal toilet. The disadvantages of open abdomen management include fluid and protein loss, ileus, fistula formation, and ventral herniation. Neither planned re-laparotomy nor open abdomen management offer survival benefits as compared with repeat laparotomy on demand.⁸⁴

Many variations in open abdomen techniques have been reported. Most often, a negative-pressure wound therapy system is utilized with a fenestrated, nonadherent material to cover the bowel, suction drains to aspirate superficial fluid, and an airtight adherent outer drape to maintain negative pressure and to prevent evisceration until adhesions form (Figs. 99-11 and 99-12). Nasogastric and urinary catheter decompression are maintained, and early enteral nutrition has been shown to provide a benefit to recovery.⁸⁵ At re-exploration, the abdomen is lavaged and loculated fluid collections are evacuated. After achieving resuscitation and adequate source control, aggressive diuresis should be initiated to reverse edema and facilitate closure of the abdomen. In a substantial percentage of patients, the fascia cannot be closed primarily. In these cases, healing by secondary intention is allowed to occur, and ventral hernias are repaired electively with absorbable mesh, biologic grafts, and skin grafts as necessary, but no earlier than 3 to 6 months after the acute episode, when all acute problems have resolved.

Antibiotic Therapy

Optimal antibiotic therapy for intraabdominal infection requires an agent or combination of agents active against gut-derived facultative enteric gram-negative bacilli and obligate anaerobes.^{18,21} The initial

FIGURE 99-11 ■ Open abdomen management of abdominal compartment syndrome. The sterile saline bag was sewn to the skin edges. Closed suction drains were placed to limit fluid accumulation, and occlusive dressing was applied to cover the abdominal wall. (Courtesy Brian J. Kimbrell, MD.)

FIGURE 99-12 ■ Open abdomen management of abdominal compartment syndrome using a VAC system. The bowel is covered with omentum if possible. Nonadherent dressing is layered under a VAC sponge, or a smaller pore sponge is used against the viscera. Negative pressure is applied to the wound closure to drain fluid, facilitate closure, and prevent evisceration. VAC, vacuum-assisted closure. (Courtesy Brian J. Kimbrell, MD.)

antibiotic therapy should be empiric and broad spectrum, as the source is not always known.

A 2005 Cochrane review of 40 studies with 5094 patients comparing 16 different antibiotic regimens for empiric first-line therapy demonstrated equivalent efficacy and made no specific recommendations based on class I evidence.³⁰ Given this equivalence (Table 99-4), the selection of an antibiotic regimen should be based on considerations of cost, availability, ease of administration, susceptibilities, and the risk of toxicity, including allergy to β -lactam agents.^{18,86}

Evidence-based guidelines for the selection of antimicrobial therapy for high-risk patients with intraabdominal infections have been formulated by the Surgical Infection Society and the Infectious Diseases Society of America.¹⁸ The most commonly accepted empiric treatment regimens for complicated intraabdominal infections include extended spectrum β -lactam/ β -lactamase agents such as piperacillin-tazobactam, carbapenems such as imipenem-cilastatin, meropenem, and ertapenem, or a third- or fourth-generation cephalosporin plus metronidazole.

TABLE 99-4

**Antimicrobial Agent Regimens
for Therapy of Serious
Intraabdominal Infections**

SINGLE AGENTS

β -Lactam/-Lactamase Inhibitor Combinations

- Ampicillin/sulbactam
- Piperacillin/tazobactam
- Ticarcillin/clavulanic acid

Carbapenems

- Imipenem-cilastatin
- Meropenem
- Ertapenem
- Doripenem

Cephalosporins

- Cefotetan
- Cefoxitin

Fluoroquinolones

- Moxifloxacin

Glycylcyclines

- Tigecycline

COMBINATION AGENTS

Aminoglycoside Plus an Antianaerobic Agent

- Amikacin, gentamicin, netilmicin, or tobramycin plus clindamycin or metronidazole

Aztreonam Plus Clindamycin

- Combination of aztreonam plus metronidazole is devoid of coverage against gram-positive cocci

Fluoroquinolone Plus Metronidazole

- Ciprofloxacin, levofloxacin, gatifloxacin, moxifloxacin

Third- or Fourth-Generation Cephalosporin Plus an Antianaerobic Agent

Data from Solomkin et al.²⁷ and Mazuski et al.²⁸

In hospital-acquired peritonitis, local antimicrobial resistance patterns should be considered. Although mortality appears to be higher when *Enterococcus* spp. are isolated from polymicrobial intraabdominal infections, there is no evidence that anti-enterococcal therapy improves outcomes.^{18,33,87} Combination therapy directed against a specific pathogen (e.g., double-drug coverage of *P. aeruginosa*) has no demonstrated benefit in sepsis and can worsen outcomes, especially leading to acute kidney injury. Newer agents, including tigecycline, ceftolazone-tazobactam, and moxifloxacin, are also equivalent in their ability to treat complicated intraabdominal infections and provide additional options in dealing with evolving bacterial resistance patterns.⁸⁸⁻⁹³

Fungal species are common components of the normal intestinal flora, and fungi are common isolates from peritoneal fluid during operations for perforated viscera. Antifungal treatment in an otherwise immunocompetent patient has not been found to improve survival.⁹⁴ Because fungal colonization usually precedes invasive infection in surgical patients, some experts advocate systemic antifungal treatment when fungal species are recovered from peritoneal fluid.^{18,94,95} Empiric antifungal therapy is warranted when fungi are isolated from two or more normally sterile sites, from the bloodstream of critically ill patients with fungal abscesses, and in immunosuppressed patients.^{2,3,18,95} In critically ill patients, initial antifungal therapy with an echinocandin (caspofungin, micafungin, and anidulafungin) is recommended over treatment with a triazole.^{18,94}

Shorter courses of antimicrobial therapy and modification of agents according to susceptibility analysis are safe in patients with adequate source control. This treatment strategy limits intraabdominal infections caused by multidrug-resistant pathogens.⁹⁶⁻¹⁰⁰ A 4-day course of

antibiotic therapy, extended until resolution of physiologic disturbances, is sufficient for the treatment of abdominal sepsis following a procedure for source control.¹⁰⁰ In hospital-acquired peritonitis, the duration of therapy is less definitive and is based upon clinical parameters such as fever, abdominal pain, leukocytosis, and the return of gastrointestinal function. Persistent sepsis should raise the possibility of inadequate source control, other nosocomial infections, or tertiary peritonitis. Broadening the antibiotic coverage or extending the duration of therapy are inappropriate strategies. Rather, sources of ongoing infection should be identified by a complete diagnostic reevaluation with physical examination, cultures, and imaging.

The concept of deescalation, where targeted narrower spectrum agents replace empiric broad-spectrum antibiotics once susceptibilities are obtained, is safe and should help to reduce the risk of the emergence of antibiotic-resistant isolates. Whereas evidence-based recommendations are unequivocal, compliance with deescalation is poor.⁹⁸ When intestinal function returns, oral antibiotics with good bioavailability can be administered to complete the course of therapy.^{18,101}

The role of antibiotics for tertiary peritonitis is poorly defined. There is little proven benefit to empiric antibiotics, and most bacterial isolates tend to be resistant to standard regimens. Empiric coverage of isolated *Enterococcus* spp. and *Candida* spp. has been well studied and is without clear benefit. Such coverage is recommended for complicated nosocomial infections in immunosuppressed patients, critically ill patients, and patients with valvular heart disease or implanted prosthetic materials.¹⁸ Antibiotics for tertiary peritonitis should be narrow spectrum and should be administered briefly. Anaerobic coverage is probably unnecessary.

COMPLICATIONS

The complications of failed source control include abscess formation, anastomotic dehiscence, surgical site infections, recurrent or persistent peritonitis, fistula formation, sepsis, and multiple organ dysfunction syndrome, which is the leading cause of death. Although an abscess, anastomotic dehiscence, and fistula formation are attributed most commonly to the failure of source control procedures, persistent peritonitis and sepsis often are attributed to the failure of host defenses.

Enterocutaneous Fistula

Enterocutaneous fistula formation is a dreaded complication of peritoneal inflammation and bowel injury. More than 80% of fistulas occur postoperatively, whereas fistulas that arise primarily from infection or irradiated bowel are rare.^{101,102} A fistula may be an occult source of

sepsis before drainage to the skin makes the diagnosis obvious. A fistula can contain an abscess cavity along its tract or exist internally as a connection between two intraabdominal structures.

When a fistula develops, initial care should be supportive. Therapy is directed at appropriate antibiotic therapy if signs of secondary infection are present, along with bowel rest, skin care, and parenteral nutritional support. Administration of octreotide may reduce fistula output, minimize fluid, electrolyte, and protein losses, and facilitate closure.^{103,104} Spontaneous closure with nonoperative therapy occurs in 30% to 50% of fistulas, usually within 3 to 4 weeks.¹⁰²

MORTALITY

Management of peritonitis and intraabdominal infection has improved substantially over the past century; however, mortality remains about 25% for critically ill patients.³ Age and the severity of illness at the time of presentation are more important predictors of mortality than the site of infection within the abdomen.³ Failure of an initial procedure for source control is more likely to result in death than infection caused by a multidrug-resistant pathogen.

Early recognition of organ dysfunction as a sign of persistent intraabdominal infection offers an opportunity to intervene while the process is still reversible.^{105,106} The key elements of management to minimize mortality include early recognition of the problem, rapid resuscitation, sufficient and timely source control procedures, and administration of appropriate broad-spectrum antibiotics.

Administration of glucocorticoids in patients with septic shock does not improve survival or prevent sepsis and increases the risk of superinfection.¹⁰⁷ Judicious transfusion of red blood cell concentrates may be of benefit as an adjunct in sepsis; however, additional data are needed for confirmation.¹⁰⁸ The concept of meticulous blood glucose control in the management of critically ill patients with sepsis has been controversial. Recent studies of medical patients indicate that this practice increases the rates of complications and mortality and should be avoided; however, there is evidence of benefit for critically ill surgical patients.¹⁰⁹⁻¹¹² Although drotrecogin alfa (activated) therapy showed promise in early studies, the PROWESS-SHOCK Study Group determined in 2012 that it does not improve early or late mortality among patients treated for septic shock.¹¹³ Polymyxin B hemoperfusion has been shown to improve outcomes in preliminary studies in Japan and Europe.^{114,115} Other adjunctive therapies of potential promise include IV IgM and IgA, recombinant thrombomodulin, interleukin-7, and thymosin $\alpha 1$.^{115,22} Further studies are under way to develop point-of-care testing for biomarkers that may predict individual responses to therapies tailored to the various manifestations of peritonitis and septic shock.¹¹⁶

KEY POINTS

1. Critically ill patients with intraabdominal infection are at high risk of treatment failure.
2. Adequate and timely resuscitation ensure tissue perfusion and oxygenation and can prevent the life-threatening complications associated with splanchnic hypoperfusion.
3. Source control must also be adequate and timely and should include débridement of devitalized tissue, closure of perforations, drainage of infected collections, reduction of bacterial and toxin burden, and the use of appropriate broad-spectrum antimicrobial therapy.
4. Acute acalculous cholecystitis is an ischemic process and is only secondarily an infection. Its diagnosis is challenging, and a high index of suspicion is required.
5. Intestinal ischemia is a dangerous and relatively common complication of critical illness, which can progress within hours to gangrene, perforation, and generalized peritonitis.
6. Early diagnosis and treatment, including operative intervention where appropriate, are essential to decrease the high mortality associated with fulminant colitis caused by *Clostridium difficile*.
7. Computed tomography is the primary radiologic modality for imaging the abdomen and pelvis in critically ill patients.
8. Percutaneous decompression of intraabdominal abscesses is successful in about 85% of cases and often can be definitive treatment. Patients who do not improve promptly following percutaneous drainage should undergo formal operative intervention without delay.

Continued

KEY POINTS—cont'd

9. Optimal antibiotic therapy for secondary peritonitis requires an agent or combination therapy active against both aerobic gram-negative bacilli and anaerobes. High-risk patients with nosocomial intraabdominal infections should be treated with broader spectrum empirical regimens, including selective use of agents effective against resistant gram-negative organisms, enterococcal species, and *Candida* species.
10. Shorter courses of antimicrobial therapy and the modification of agents once susceptibilities are available are safe in patients with adequate source control and decrease the risk of infections caused by multidrug-resistant pathogens.
11. Complications associated with inadequate source control include abscess formation, anastomotic dehiscence, surgical site infection, recurrent or persistent (secondary or tertiary) peritonitis, fistula formation, abdominal compartment syndrome, sepsis, and multiple organ dysfunction syndrome.
12. Neither planned re-laparotomy nor open abdomen techniques offer survival benefits when compared with on-demand re-laparotomy in achieving adequate source control.
13. Multiple organ dysfunction syndrome is present in virtually every patient who dies from intraabdominal infection.

ANNOTATED REFERENCES

- Ballinger AE, Palmer SC, Wiggins KJ, et al. Treatment for peritoneal dialysis-associated peritonitis. *Cochrane Database Syst Rev* 2014;(4):CD005284.
This Cochrane review of 42 studies with 2433 patients investigated intraperitoneal (IP) versus intravenous administration of antibiotic regimens for peritoneal dialysis catheter-associated peritonitis. The best available evidence suggests that IP antibiotics, including glycopeptide antibiotics, are superior to intravenous antibiotics in reducing treatment failure.
- Dellinger RP, Levy MM, Carlet JM, et al. Surviving Sepsis Campaign: International guidelines for management of severe sepsis and septic shock: 2008. *Intensive Care Med* 2008;34:17-60.
This summary provides evidence-based guidelines for the management of severe sepsis, including specific recommendations regarding the management of peritonitis. The targets include early goal-directed resuscitation, prompt imaging studies, initiation of broad-spectrum antibiotics in the first hour of recognition, deescalation and shorter durations of antibiotic therapy, prompt identification of a specific anatomic site of infection, and expeditious implementation of source control measures as soon as possible following resuscitation.
- De Waele JJ, Ravyts M, Depdt P, et al. De-escalation after empirical meropenem treatment in the intensive care unit: fiction or reality? *J Crit Care* 2010;25:641-6.
Deescalation of antimicrobial therapy is advocated to reduce the use of broad-spectrum antibiotics in critically ill patients, but application of this strategy in daily clinical practice is variable. In this study, deescalation after empirical treatment with meropenem occurred in less than one-half of the patients. The reasons for this include the absence of conclusive microbiology and colonization.
- Finfer S, Chittock DR, Su SY, et al. NICE-SUGAR Study Investigators. Intensive versus conventional glucose control in critically ill patients. *N Engl J Med* 2009;360:1283-97.
This study reports on the results of the 2009 NICE-SUGAR trial (Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation), a large, international randomized controlled trial of 6100 patients including both surgical and medical intensive care unit patients. The study found an increased absolute risk of death of 2.6% at 90 days as well as an increased risk of complications due to severe hypoglycemia.
- Mazuski J, Solomkin J. Intraabdominal infections. *Surg Clin North Am* 2009;89:421-37.
*Nonoperative management is safe and appropriate for highly selected patients with a well-controlled infectious source. Community-acquired intraabdominal infections should receive narrower-spectrum agents that provide coverage against the common gram-negative and gram-positive aerobic and obligate anaerobic microorganisms. Higher risk nosocomial infections should be treated with broader spectrum agents to treat resistant gram-negative organisms, *Enterococcus* spp., and *Candida* spp. Shorter durations of empirical antimicrobial therapy are both safe and effective, with treatment generally limited to no more than 4 to 5 days in most patients who demonstrate satisfactory clinical response.*
- Ranieri VM, Thompson BT, Barie PS, et al. Drotrecogin alfa (activated) in adults with septic shock. *N Engl J Med* 2012;366:2055-64.
The PROWESS-SHOCK randomized controlled trial demonstrated that, despite preliminary evidence to the contrary, activated protein C did not significantly reduce mortality at 28 or 90 days in 1697 patients with septic shock.
- Rivera-Sanz G. Percutaneous abdominal abscess drainage: a historical perspective. *AJR Am J Roentgenol* 2008;191:642-3.
Since its first reported use 30 years ago, percutaneous abscess drainage has become a standard of care for the treatment of abdominal and thoracic collections, replacing more invasive surgical procedures in all but the most difficult cases.
- Sailhamer EA, Carson K, Chang Y, et al. Fulminant *Clostridium difficile* colitis: patterns of care and predictors of mortality. *Arch Surg* 2009;144:433-9.
*The incidence and severity of *C. difficile* infections (CDI) are increasing. Fulminant CDI is a life-threatening disease, and early diagnosis and treatment are essential. Early surgical intervention with subtotal colectomy should be used in patients who are unresponsive to medical therapy. Mortality was notably decreased when patients had no more than 6 days of medical treatment.*
- Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Surg Infect (Larchmt)* 2010;11:79-109.
Evidence-based guidelines for intraabdominal infection were prepared by an expert panel of the Surgical Infection Society and the Infectious Diseases Society of America. These replace guidelines previously published in 2002 and 2003.
- van Santvoort HC, Besselink MG, Bakker OJ, et al. Dutch Pancreatitis Study Group. A step-up approach or open necrosectomy for necrotizing pancreatitis. *N Engl J Med* 2010;362:1491-502.
A minimally invasive "step-up" approach to manage infected pancreatic necrosis may decrease the morbidity associated with open necrosectomy. This approach consists of percutaneous drainage followed, if necessary, by minimally invasive retroperitoneal necrosectomy; 35% were treated with percutaneous drainage only. New-onset multiple organ dysfunction syndrome, incisional hernias, and new-onset diabetes mellitus occurred less frequently in patients randomized to this less invasive study arm. The rate of death did not differ significantly between the groups.
- Wong PE, Gilliam AD, Kumar S, et al. Antibiotic regimens for secondary peritonitis of gastrointestinal origin in adults. *Cochrane Database Syst Rev* 2005;(2):1-78.
This Cochrane review compares 40 studies of 16 different antibiotic regimens for peritonitis in 5094 patients. All regimens were comparable in terms of clinical success and mortality. Other factors such as local guidelines and preferences, ease of administration, costs, and availability must therefore be used for antibiotic selection.

Obstructions of the small bowel can be classified into two categories: nonmechanical and mechanical. Nonmechanical obstruction (e.g., ileus, pseudo-obstruction) is defined as a disturbance in motility preventing luminal contents to pass with coordinated peristalsis. Mechanical obstruction is the inability for contents to move forward due to luminal obstruction. Further classification is based on the presence of vascular compromise and ischemia.

Functional obstruction (ileus) has an annual incidence of 20%,¹ while mechanical obstruction has an annual incidence of 2% to 9%, or roughly 1 in 3000.² Nearly 70% of small bowel obstructions are due to adhesions from previous surgery.³ Risk factors for the development of adhesions include pelvic surgery, emergency laparotomy, peritonitis, penetrating trauma or prior bowel obstruction (i.e., stricture or luminal narrowing, anastomosis). Other causes of obstruction are neoplastic (20%) and hernia (10%), with the remaining cases occurring from volvulus, inflammatory changes, or other causes (gallstone ileus, trauma, external mass effect, endometriosis, foreign body).⁴

In a recent review of 87 studies including 110,076 patients, the incidence of adhesive small bowel obstruction (aSBO) following abdominal surgery is 2.4%.⁵ Reviewing patient data collected over 10 years, aSBO accounts for greater than 300,000 annual hospital admissions, which translates into roughly 850,000 inpatient days, with a total cost exceeding \$1.3 billion annually.⁶ A nationwide inpatient sample study performed in 2009 enrolled 27,046 patients with aSBO and demonstrated that a delay in surgery for patients with a complete obstruction due to adhesive disease is associated with an increased length of stay and increased mortality. A delay of 4 days is associated with a 64% increased risk of finding nonviable bowel at time of exploration and a fourfold increase in overall mortality.⁷ This statistic highlights the importance of early recognition and diagnosis of a complete obstruction to facilitate early surgical intervention (<72 hours). The idea of early surgical therapy for aSBO is substantiated by another review of 9297 patients from the NSQIP database from 2005 to 2011.⁸ Keenan et al.⁷ observed that patients who underwent surgery after 3 days had an increased overall 30-day morbidity and those who waited more than 4 days had an increased overall length of stay. Thus, the World Society of Emergency Surgery set guidelines in 2013 for the management of aSBO recommending that nonoperative management should not exceed 3 days due to the increase in mortality.⁹

Multiple surgical studies have investigated the various methods to aid in early diagnosis of complete obstruction, either by clinical or radiographic criteria. The goal of early recognition is to decrease delay to definitive surgical treatment and to reduce additional morbidity and mortality.

■ DIAGNOSIS

Diagnosis of a small bowel obstruction or ileus is based on a combination of patient history and imaging. The main objective in the diagnosis of a bowel obstruction is to differentiate between a functional ileus and a mechanical obstruction. Once a mechanical obstruction is identified, further classification of patients with partial versus complete bowel obstruction is based on a combination of clinical exam, physiologic status, and imaging.

Symptoms include intermittent cramping abdominal pain, progressing to constant pain, nausea, vomiting, distention, and obstipation. Ileus and pseudo-obstruction are generally associated with an additional clinical diagnosis such as recent infection (pneumonia

or urinary tract infection), electrolyte imbalance, or a recent surgical procedure. Laparotomy, orthopedic, and vascular procedures are often associated with prolonged ileus or colonic inertia. Plain films frequently display air fluid levels and dilation of the small bowel with decreased or no air in the colon and rectum. Unfortunately, these signs are present only 20% of the time.¹⁰

Computerized tomography (CT) scan may be more specific and sensitive for the detection of ileus versus small bowel obstruction and will give suggestions of vascular compromise. A transition from a dilated loop to a decompressed segment is the most common finding in bowel obstruction. This transition point is absent with an ileus or pseudo-obstruction. Signs associated with vascular ischemia are thickened bowel walls (>3 mm) or bowel wall edema, portal venous gas, ascites, and decreased enhancement of bowel wall.¹¹ Target or swirl signs suggest volvulus or internal hernia, which can lead to strangulation. CT scan may also be able to identify other potential causes of small bowel obstruction such as hernia or neoplastic processes. Overall, the sensitivity in diagnosis of obstruction with CT scan is 94%, with a specificity of 96%; the sensitivity of plain films is approximately 50% to 70%.¹¹

Differentiation between a partial or complete obstruction is difficult. In a recent study of aSBO, resuscitated patients underwent initial CT scan with intravenous contrast to determine the presence of vascular compromise; those with signs on imaging were directed into the surgery cohort. PO contrast was not used initially to reduce risk of aspiration and to improve diagnostic efficacy with future contrast studies. Those patients with signs and symptoms consistent with aSBO without peritonitis or CT evidence of ischemia were placed in the nonsurgery cohort.¹² Those with symptoms of peritonitis, suspicion of ischemic bowel, with abdominal tenderness, fever, tachycardia, leukocytosis, or metabolic acidosis received urgent surgical intervention after adequate resuscitation without additional diagnostics.¹²

Patients in the nonsurgery group with clinical signs of obstruction and without vascular compromise on CT were observed with serial exams and monitored for resolution of obstruction. Once physiologically improved, an osmotically active oral contrast was administered, and serial films were obtained to monitor for resolution of partial obstruction or identification of complete obstruction.¹³

A recent review combining resuscitation, bowel decompression, and administration of an oral contrast agent found a positive predictive value of 99% for nonsurgical resolution if contrast reached the colon within 24 hours.¹⁴ Lack of contrast in the colon at 24 hours was consistent with a diagnosis of complete obstruction and an indication for operative intervention. The administration of contrast can be both diagnostic for complete obstruction, therapeutic time to resolution, and overall hospital length of stay.¹⁴

■ TREATMENT

Treatment arms differ based on the diagnosis of pseudo, partial, or complete obstruction. Morbidity and mortality are directly affected when definitive treatment of a mechanical obstruction is delayed.¹⁴ Ileus and pseudo obstruction are treated primarily by treating the underlying cause. Correction of electrolyte abnormalities and treatment for infectious etiology result in resolution the majority of the time. Stool softeners and motility agents should be used with caution and in a monitored setting when conservative measures have not resulted in resolution. Pseudo-obstruction is more complex and requires confirmation that an

obstruction is absent. An aggressive bowel regimen with enemas and direct decompression is often necessary. Pharmacologic agents such as neostigmine can be used to promote colonic motility if medical contraindications and mechanical obstruction are absent.

The treatment pathway for mechanical obstruction depends on the clinical picture of the patient. [Figure 100-1](#) depicts an algorithm for managing the patient presenting with symptoms of aSBO.¹² Nonsurgical management is appropriate for patients with a partial obstruction or those without signs suggestive of strangulation or closed loop obstruction. Management involves isotonic fluid resuscitation, bowel decompression, and serial examination. When physiologically stable, the use of an oral contrast challenge may further guide therapy. Frequent abdominal exams are necessary as a clinical change or progression to ischemia mandates operative intervention, as does failure to pass Gastrografin at 24 hours. Those with concerns for strangulation based on CT scan or those with physical exam evidence of peritonitis should receive resuscitation and gastric decompression prior to prompt surgical therapy. The presence of complete obstruction at any time requires operative correction when physiologically stable.

The World Society of Emergency Surgery and EAST practice guidelines¹⁵ both advocate for definitive therapy of complete obstruction within 72 hours of presentation. The presence of contrast within the colon had 96% sensitivity, 98% specificity, 99% positive predictive value and 90% negative predictive value for successful resolution of bowel in cases suggestive of partial obstruction.¹⁶

The objective of surgical intervention is relief of obstruction and assessment of bowel viability. Assessment may include the use of Doppler signals or injection of fluorescein and Wood lamp

examination with the possibility of a second exploration if indicated or if further resuscitation is required. Evaluation of the entire bowel is essential to rule out multiple transition points.

Limited evidence in the medical literature addresses the types of surgical interventions. The use of laparoscopy may be appropriate in select patients. The advantages include earlier return of bowel function, fewer wound complications, lower narcotic use, decreased length of stay, and decreased development of postoperative adhesions.⁹ A national inpatient sample of 6165 patients found a significant decrease in postoperative complications, hospital length of stay, and overall costs of aSBO managed with laparoscopic adhesiolysis.¹⁷ The conditions favoring the use of laparoscopy are mild distention, proximal obstruction, and anticipated single band obstruction based on a clinical history of recent pelvic surgery.¹⁸

Currently, there are no controlled prospective studies to support or refute the use of antibiotics or long-tube decompression devices in the management of small bowel obstruction.¹⁸ Therefore, the use of nasal gastric decompression and isotonic fluid hydration remains the standard of care.

Roughly 80% of those presenting with partial small bowel obstruction have improvement in symptoms and resolution with conservative management alone.¹⁸ Those treated conservatively will have a recurrence rate approaching 20% to 40% within the first year, while early surgical therapy has been shown to reduce recurrence to 6% to 12%.²

Surgical intervention carries its own risks of morbidity, including the formation of fistulas and adhesions, wound infections, and development of a short gut from multiple small bowel resections. A surgical technique with minimal tissue injury and the use of commercially available adhesion barriers (Seprafilm, Interceed, and Adept) may decrease the formation of adhesions; however, there is currently insufficient data to support their global use.

Certain populations present with bowel obstructions not previously mentioned that warrant special consideration. For instance, patients with inflammatory bowel disease (Crohn's) will have higher rates of conservative therapy, incorporating the use of steroids and immune modulation if without infection.¹⁸ Another special case is the trauma patient with an intramural hematoma involving the duodenum, where management requires parenteral nutrition and proximal decompression. Stricture formation necessitating surgical revision or reconstruction rarely occurs.¹⁸

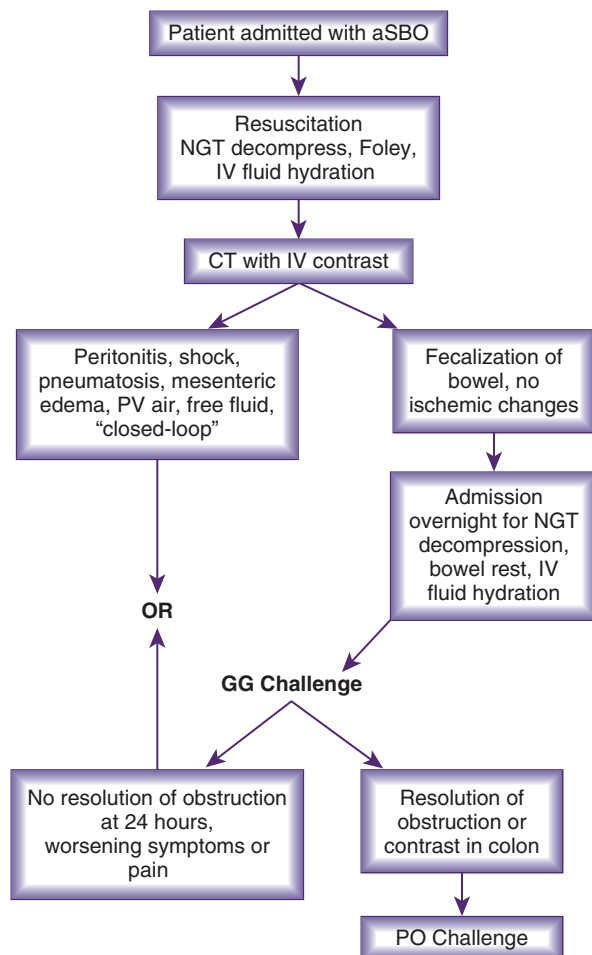

FIGURE 100-1 ■ Patient admitted with adhesive small bowel obstruction.

KEY POINTS

1. CT scan has 98% sensitivity for identification of small bowel obstruction and detecting presence of strangulation.
2. Patients with signs and symptoms of peritonitis (fever, tachycardia, metabolic acidosis, and continuous pain) should undergo early urgent surgical therapy.
3. Patients without peritonitis may be conservatively managed with hydration, bowel decompression, and oral contrast challenge.
4. Administration of oral contrast is both diagnostic and therapeutic for adhesive small bowel obstruction, especially in partial obstruction.
5. Failure to pass contrast into the colon within 24 hours of administration demonstrates complete obstruction, and use of a surgical approach is appropriate.
6. Increased morbidity and mortality are associated with bowel resection and strangulation if surgical therapy is delayed for more than 72 hours.
7. Synthetic materials to prevent adhesion formation are of limited utility.

Acute megacolon refers to a syndrome defined by abnormal colonic distention in the absence of mechanical obstruction. Megacolon may be a manifestation of Ogilvie's syndrome or toxic megacolon. The sequelae of these disorders result in diffuse colonic dysmotility. Ogilvie's syndrome is an eponym for acute colonic pseudo-obstruction.^{1,2} Critical illness-related colonic ileus (CIRCI) is characterized by constipation for several days without marked colonic distention and may herald the development of Ogilvie's syndrome.³ Ogilvie's syndrome is believed to be a functional disturbance of colonic motility and is often observed in hospitalized patients as a result of hemodynamic, metabolic, pharmacologic, inflammatory or postoperative conditions.⁴ In toxic megacolon, the distention is caused by severe colitis and is associated with systemic manifestations or toxicity. Although usually attributed to inflammatory bowel disease (IBD), most notably ulcerative colitis, toxic megacolon may manifest in the critically ill as a complication of severe infectious colitis, most frequently caused by *Clostridium difficile*. Both Ogilvie's syndrome and toxic megacolon are medical emergencies that, if left untreated, result in intestinal barrier failure, colonic ischemia, perforation, and multiple organ dysfunction. This chapter focuses on toxic megacolon and Ogilvie's syndrome in critically ill patients admitted to intensive care units (ICUs) and provides management and prevention strategies for each disease process.

CLINICAL FEATURES

Ogilvie's Syndrome or Acute Colonic Pseudo-obstruction

The clinical features of Ogilvie's syndrome include abdominal distention with or without abdominal pain in hospitalized or institutionalized patients with serious underlying medical and surgical conditions.^{2,5,6} Patients usually present with constipation; however, passage of flatus or stool is reported in up to 40% of patients.² Bowel sounds may be normal, diminished, or hyperdynamic. Leukocytosis and fever are more common in patients with ischemia or perforation but also occur in those who have not developed these complications. According to Laplace's Law, the pressure required to stretch the walls of a hollow viscus decreases in inverse proportion to the diameter.⁷ Therefore, progressive colonic distention causes the highest tension in the wall of the cecum and is thus most likely to be the site of perforation. The risk of cecal perforation increases sharply when the cecal diameter is greater than 12 cm and when this distention has been present for longer than 6 days.⁸ A diameter of 9 to 12 cm has been suggested as a sign of impending perforation.^{2,4} If the diagnosis and treatment are delayed, progressive distention may cause peritoneal signs, abdominal compartment syndrome, respiratory compromise, sepsis, ischemia, perforation, multiple organ failure, and death.

Toxic Megacolon

Toxic megacolon is the late, life-threatening complication of inflammatory or infectious colitis. Patients present with fever, leukocytosis, abdominal distention and tenderness, with or without signs of local or generalized peritonitis. Both IBD and infectious colitis classically present with diarrhea, but constipation may herald the onset of megacolon, delaying diagnosis. In addition to these findings, patients may

present with dehydration, altered consciousness, electrolyte disturbances, hypoalbuminemia, and hypotension. In severe cases, septic shock and multiple organ failure may ensue.^{9,10} Factors that may trigger or predispose to the development of toxic megacolon have been identified; these include severe hypokalemia, discontinuation or rapid tapering of corticosteroids, sulfasalazine, or mesalazine, use of antidiarrheal agents, and use of antidepressants.¹¹ Barium enema and colonoscopy may cause worsening distention that further impairs colonic blood supply, leading to increased transmural bacterial translocation, and should be avoided.

PATHOGENESIS OF ACUTE MEGACOLON

Colonic Ileus and Ogilvie's Syndrome

The pathophysiology of Ogilvie's syndrome is not fully understood. The current literature suggests an imbalance in the autonomic regulation of the colonic motor function, leading to excessive parasympathetic suppression and sympathetic stimulation. This results in an aperistaltic colon.^{12,13} In addition to autonomic dysregulation, neurotransmitters (e.g., substance P and vasoactive intestinal polypeptide [VIP]), inflammatory mediators (e.g., tumor necrosis factor [TNF], interleukin 1 [IL-1]), metabolic derangements, and pharmacologic interventions also play crucial roles in the development of Ogilvie's syndrome.¹⁴

Postoperative motility disturbances are inevitable after abdominal surgery and result from a complex interaction of neurogenic and inflammatory mechanisms. The extent of parasympathetic suppression and sympathetic activation depends on the amount of surgical stimulation, as demonstrated by Bueno et al. in experimental studies in dogs.¹⁵ Surgical manipulation triggers two different, distinct phases of postoperative ileus. The first or early phase is neurally mediated and is activated during and immediately following surgery. During this phase, intestinal manipulation initiates the release of norepinephrine via the sympathetic nerves from the spinal cord, as well as nitric oxide (NO) and VIP release via vagal nerve stimulation, abolishing the motility of the entire gastrointestinal (GI) tract.^{16,17} This phase ceases once the abdomen is closed. The second, long-lasting phase of postoperative ileus involves the inflammation of the intestinal muscularis. During this phase, activation of peritoneal mast cells triggers the release of vasoactive and proinflammatory substances such as histamine and proteases, which recruit leukocytes and temporarily increase mucosal permeability. This allows luminal bacteria or bacterial products to enter the lymphatics. This likely represents the key event that triggers the next stage of the inflammatory cascade, which is activation of the resident macrophages. Once activated, the resident macrophages release cytokines such as TNF and cause the subsequent up-regulation of inducible NO synthetase and cyclooxygenase-2, further blunting the contractile response of the inflamed tissues.¹⁸ In addition, *in vivo* animal studies have demonstrated that endogenous opioids released peripherally can modulate GI motor and secretory functions.¹⁹ Opioid receptors are stimulated by endogenous opioids, which are secreted locally upon stress. Once activated, they inhibit acetylcholine release from motor neurons and promote transmitter release from inhibitory neurons.²⁰ In addition to stimulation by endogenous opioids, exogenous opioids, commonly used for analgesia, also act upon peripheral opioid receptors in the GI tract, inhibiting GI motility.

CIRCI may be related to circulating bacteria or bacterial products and/or proinflammatory cytokines, following a similar mechanism as previously described. Colonic ileus also has been associated with ischemia-reperfusion injury, causing energy deficit, *functio laesa*, and oxidant-mediated tissue damage. Finally, distal colonic distention induces inhibition of proximal colonic motility, the so-called colocolonic reflex, thereby perpetuating a vicious cycle.²¹

■ PREDISPOSING FACTORS

Ogilvie's Syndrome

Acute colonic pseudo-obstruction was first described by Sir William Heneage Ogilvie in two patients who had retroperitoneal tumors invading the celiac plexus, which led him to suggest sympathetic deprivation as the etiology of the massive distention.⁵ The vast majority of patients presenting with Ogilvie's syndrome have the syndrome in association with a predisposing factor. Clinical factors predisposing to Ogilvie's syndrome are summarized in [Box 101-1](#).^{1,2,6} In a large retrospective series of 400 patients, Vanek et al. reported that the most common predisposing conditions associated with Ogilvie's syndrome were nonoperative trauma (11%), infections (10%), and cardiac disease (10%).⁶ Although nonsurgical factors predisposing to Ogilvie's syndrome are common, surgical operations remain the most common cause of this syndrome. Of these operations, Ogilvie's syndrome is

most likely to occur after obstetric/gynecologic, abdominal/pelvic, trauma, orthopedic/spine, and cardiac procedures. These procedures account for 50% to 60% of all Ogilvie's cases.²² Exogenous catecholamines have dose-dependent effects on intestinal motility; low doses promote and high doses suppress motility. α -Adrenergic agonists and dopamine are stronger inhibitors of acetylcholine release than β -adrenergic agents. Dopamine, in addition to inhibiting upper GI motility, also inhibits distal colonic motility. Antipsychotic agents such as clozapine, haloperidol, and olanzapine have been associated with life-threatening forms of Ogilvie's syndrome.²³ One explanation of these GI side effects is the antimuscarinic properties of these drugs. Opioids suppress GI motility through activation of μ -opioid receptors, which inhibit the release of acetylcholine from the myenteric plexus. The outcome of this interaction is the decreased levels of cyclic adenosine monophosphate (AMP) and calcium, with a reduction in the excitatory neurotransmitter release that ultimately leads to decreased peristalsis.^{12,20} Opioid agonists inhibit GI wall motility, impair reabsorption of fluid from the lumen, and also impair relaxation of the internal anal sphincter.²⁴ Additional predisposing factors such as severe metabolic derangements, sepsis, GI infections, and spinal cord injuries have also been implicated in the development of Ogilvie's syndrome.

Toxic Megacolon

Acute toxic megacolon was originally described in 1950 as a complication of IBD. The incidence of toxic megacolon in IBD has substantially decreased with the advances in the management of severe colitis. Over the course of the past decade, the list of etiologic factors has been expanded by a vast array of inflammatory and infectious conditions; bacterial colitides such as *C. difficile*, *Staphylococcus* spp., *Salmonella* spp., *Shigella* spp., and *Campylobacter* spp., as well as viral (e.g., cytomegalovirus, human immunodeficiency virus, and herpesvirus) and parasitic (*Entamoeba*) infections have all been associated with toxic megacolon.^{25,26} However, the most common cause of acute toxic megacolon in the critically ill is pseudomembranous colitis caused by *C. difficile*. While many conditions have been associated with the development of toxic megacolon, its precise pathophysiology is not fully understood. The causes of toxic megacolon are summarized in [Box 101-2](#).

C. difficile Infection

C. difficile is a gram-positive, spore-forming, toxin-producing, anaerobic rod bacterium. Less than 5% of the healthy adult population is colonized with this bacterium.²⁷ An estimated 30% of hospitalized patients become colonized with *C. difficile*, although most of these patients remain asymptomatic. Pathogenic strains produce two major exotoxins: toxin A (enterotoxin/Tcd A) and toxin B (cytotoxin/Tcd B).²⁸ Purified toxin A possesses potent enterotoxic and proinflammatory activities. Toxin B has been previously reported to

BOX 101-1

Clinical Factors Predisposing to Ogilvie's Syndrome or Acute Colonic Pseudo-obstruction

CARDIOVASCULAR

- Heart failure, stroke
- Gut ischemia

CRITICAL ILLNESS

- Severe sepsis
- Acute pancreatitis
- Shock or hypoxemia

POSTOPERATIVE STATE OR TRAUMA

- Intestinal manipulation
- Peritonitis
- Immobility and dehydration
- Vertebral, pelvic, or hip fracture/surgery
- Retroperitoneal hematoma

METABOLIC FACTORS

- Hypokalemia and hyperglycemia
- Hypothyroidism, diabetes mellitus
- Liver or renal failure
- Amyloidosis

DRUGS

- α -Adrenergic agonists, dopamine¹⁸
- Clonidine and dexmedetomidine³⁶
- Opioids
- Anticholinergics, calcium channel antagonists
- Antipsychotics^{39,40}
- Antidepressants
- High-dose phosphodiesterase inhibitors

GASTROINTESTINAL INFECTIONS

- Cytomegalovirus, herpes zoster
- Tuberculosis

NEUROLOGIC

- Transsection of the spinal cord
- Low spinal cord disease
- Parkinson's disease

OBSTETRIC

- Cesarean section

Disorders Associated With Toxic Megacolon

INFLAMMATORY BOWEL DISEASE

- Ulcerative colitis
- Crohn's disease

INFECTIOUS COLITIS

- *Salmonella*, *Shigella*, amebic colitis
- *Clostridium difficile*
- Cytomegalovirus colitis
- HIV infection

CANCER CHEMOTHERAPY

ISCHEMIA

HIV, human immunodeficiency virus.

BOX 101-3**Factors Associated With Colonization and Subsequent Infection With *Clostridium difficile*****DISRUPTION OF INDIGENOUS MICROFLORA**

- Antibiotics suppressing indigenous microflora
- Cancer chemotherapeutics with antimicrobial activity
- Preoperative bowel preparation

OPPORTUNITY OF INFECTION

- Prolonged hospital stay

MICROBIAL FACTORS

- Toxigenicity and adhesion

DIMINISHED GASTROINTESTINAL DEFENSE

- Reduced or suppressed gastric acid secretion
- Parenteral nutrition
- Postpyloric enteral nutrition
- Gastrointestinal surgery

ANTIBODY RESPONSE OF THE HOST**POOR UNDERLYING CONDITION**

- Old age
- Cancer
- Renal insufficiency
- Long-term use of corticosteroids
- Bedridden state

exhibit no enterotoxic activities; however, recent studies have described enterotoxic and proinflammatory activities in human intestinal xenografts in mice.²⁹ It has been postulated that toxins A and B act synergistically to activate cell-signaling molecules, including transcription factor, nuclear factor- κ B, and mitogen-activated protein kinases in monocytes, leading to the production and release of proinflammatory cytokines. Toxin A leads to an increased secretion of fluid within the digestive tract, mucosal inflammation, and structural damage. Toxin B, in most cases, is responsible for the major problems associated with infection and is estimated to have 10 times more impact on the GI tract than toxin A.³⁰ Recently, a hypervirulent strain has been identified. This strain, referred to as *NAP1/BI/027*, is responsible for outbreaks of highly virulent pathogens. A deletion in this strain's *tcdC* gene, which is a negative regulator of toxin production, causes the production of both toxins A and B to increase by 16- to 23-fold.^{27,31} This strain is also more resistant to fluoroquinolones, has hypersporulation capacity, and produces an additional toxin, toxin C. This hypersporulation capacity potentially accounts for the enhanced transmission in hospitals compared with previous strains.

Colonial proliferation of *C. difficile* is thought to occur when the bacterial environment has been altered by current or previous exposure to antibiotics.²⁷ Historically, antibiotics such as clindamycin, cephalosporins, and certain penicillins were most commonly associated with *C. difficile* colitis. More recently, fluoroquinolones have been implicated as a more common cause of this infection. The risk of being infected with this organism increases with prolonged hospital stay and institutionalization, and the organism may be spread by nosocomial transmission. It has been postulated that susceptibility is further increased with the concurrent use of gastric acid-inhibiting drugs, which can facilitate increased survival of the *C. difficile* spores. A complete list of factors associated with *C. difficile* infection (CDI) can be found in [Box 101-3](#).

DIAGNOSIS OF ACUTE MEGACOLON

The diagnosis of acute megacolon is suggested by the clinical presentation. A thorough history and physical exam should be obtained for all patients with acute abdominal distention and may help identify the underlying cause ([Boxes 101-2 and 101-3](#)). Mild cases typically present with abdominal pain and cramping, constipation or diarrhea, and low-grade fever. More severe cases may present with significant abdominal

FIGURE 101-1 ■ Plain abdominal radiograph of patient with respiratory insufficiency due to severe emphysema and Ogilvie's syndrome 10 days after dynamic hip screw implantation for femoral fracture. Dilatation is most pronounced in cecum and ascending colon. Gas and fecal pattern in distal colon is normal. Patient was successfully treated with intravenous neostigmine.

tenderness and signs of systemic inflammation, such as fever, leukocytosis, and electrolyte abnormalities. Plain abdominal radiography is essential in the diagnostic workup, which can show varying degrees of colonic dilation. Dilation is most pronounced in the cecum, ascending colon, and right transverse colon. The cecal diameter may range from 6 to 20 cm. "Cutoffs" are common at the splenic flexure and descending colon ([Fig. 101-1](#)), and dilation of the left colon may also occur ([Fig. 101-2](#)). The distribution of colonic dilation may be caused by different origins of the proximal and distal parasympathetic nerve supply of the colon. Air/fluid levels may be seen in the small bowel, indicating a paralytic ileus. The differential diagnosis of acute colon distention in a critically ill patient should include mechanical obstruction, infectious colitis with toxic megacolon, and Ogilvie's syndrome. Prompt evaluation of a patient with acute megacolon should involve excluding mechanical obstruction and other causes of toxic megacolon such as *C. difficile* colitis and assessment for signs of peritonitis or perforation, which indicates a surgical emergency. Mechanical obstruction is excluded if air is visible in all colonic segments, including the rectosigmoid junction. If the diagnosis is in question, mechanical obstruction can be excluded by performing a water-soluble contrast enema or computed tomography (CT) scan. The water-soluble contrast medium creates an osmotic effect and may be therapeutic in decompressing the colon. On contrast enema, the colonic haustral and mucosal pattern is maintained in Ogilvie's syndrome, whereas the pattern is disturbed or lost in toxic megacolon. Pneumatosis of the bowel wall or free intraperitoneal air on CT scan indicates the need for urgent surgical consultation.

If toxic megacolon is suspected, fresh stools should be submitted for laboratory culture and the stools should be screened for the presence of toxigenic *C. difficile*. Commercially available nucleic acid

FIGURE 101-2 ■ Plain abdominal radiograph of a patient with Ogilvie's syndrome 11 days after surgery for a ruptured aneurysm of the abdominal aorta. Dilatation (probably due to ischemia) is present in both the right and left colon. The syndrome was resolved with vasodilators and intravenous neostigmine.

amplification tests (NAAT) such as PCR for the rapid detection of CDI are inexpensive, highly sensitive, and allow results to be available within hours. These tests should only be utilized in patients with documented diarrhea. An alternative method for the detection of CDI requires a two-step procedure. The patient should first be screened for the presence of glutamate dehydrogenase (GDH), an enzyme produced by *C. difficile* in relatively large amounts compared with toxins A and B. Although GDH testing is sensitive, it is not as specific for CDI, because this enzyme is produced by both toxigenic and nontoxigenic organisms. GDH-negative specimens require no further testing. GDH-positive specimens must undergo additional screening either by NAAT or by toxins A and B enzyme immunoassay (EIA) testing followed by NAAT if the EIA results are discordant.³² The final results take 2 to 5 days. After an initial negative result, repeat testing within 48 hours should be discouraged, as conversion to a positive result occurs in less than 5% of patients.³³ Studies have shown that both toxin A and B EIA and toxigenic cultures may remain positive for as long as 30 days in patients who have resolution of symptoms. Therefore, "test for cure" studies may complicate clinical care, resulting in unnecessary prolongation of treatment, and therefore should not be performed. Surveillance cultures of feces are advocated to detect other pathogens such as enterotoxin-producing *Clostridium perfringens*, *Staphylococcus aureus*, and *Klebsiella oxytoca*. Blood cultures should be obtained from any patient presenting with toxic megacolon.

Limited endoscopy (e.g., flexible sigmoidoscopy) with biopsy may be valuable in differentiating etiologic causes; however, full colonoscopy bears the high risk of perforation and is therefore contraindicated. IBD is characterized by diffusely abnormal crypt structure, whereas normal crypt architecture is seen in bacterial colitis. Mild cases of *C. difficile* colitis are associated with nonspecific findings of colitis, such as friability of the mucosal surface. In severe cases, focal ulcerations

BOX 101-4

Strategies to Prevent Ogilvie's Syndrome in the Critically Ill

- Early resuscitation of the circulation
- Minimizing prolonged infusion of high doses of α -adrenergic drugs
- Minimizing the use of dopamine
- Minimizing the prolonged use of opioids
- Use of thoracic epidural anesthesia
- Minimally invasive or laparoscopic surgery
- Selective decontamination of the digestive tract
- Avoiding antibiotics that disrupt the growth of anaerobic fecal bacteria
- Early oral or enteral feeding
- Avoidance of proton-pump inhibitors
- Early mobilization and ambulation
- Promoting timely defecation

covered by purulent material or pseudomembranes interspersed with normal intervening mucosa may be seen. While pathognomonic for CDI, these lesions are not uniformly present and may not be present throughout the entire colon.

MANAGEMENT

Ogilvie's Syndrome

Medical Management

An essential concept to the management of Ogilvie's syndrome is prevention. Many hemodynamic, surgical, and metabolic derangements have been implicated in the development of Ogilvie's syndrome. Strategies to prevent Ogilvie's syndrome in the critically ill are highlighted in [Box 101-4](#). Life-threatening complications may occur if treatment is delayed. Supportive therapy is the preferred initial management and should be instituted in all patients. Concomitantly, conditions that impair colonic motility must be corrected. Patients should be made *nil per os* and intravenous fluids administered to restore euvolemia. Nasogastric decompression should be initiated in patients with concomitant paralytic ileus. Electrolyte and metabolic abnormalities, including phosphorous, magnesium, calcium, and thyroid functions, should be corrected via parenteral administration. Blood cultures and empirical antibiotics should be administered if sepsis is clinically suspected. Offending medication use, such as opioids, anticholinergic agents, norepinephrine, and dopamine, should be minimized or discontinued if possible. Optimal body positioning, such as prone positioning with the hips elevated on pillows or the knee-chest position with the hips held high, often aids in spontaneous evacuation of flatus.^{2,5} These positions should be alternated with the right and left lateral decubitus positions regularly, when feasible. The use of a rectal tube may also aid in decompression. Serial abdominal examinations, assessing for signs of peritonitis or free perforation, should be performed, and plain abdominal radiographs should be obtained every 12 hours. Osmotic laxatives lead to increased gas formation in the colon and should be avoided.³⁴ The reported success of conservative management is variable, with rates from 20% to 92%.³⁵ Deterioration or non-resolution of symptoms despite maximal medical therapy within 48 to 72 hours of initiating therapy should prompt reconsideration of the management plan.

If these measures are ineffective, intravenous neostigmine is the drug of choice. Neostigmine is an anticholinesterase parasympathomimetic agent commonly used for postoperative reversal of nondepolarizing neuromuscular blockade and in the treatment of myasthenia gravis. Parasympathetic stimulation can result in bradycardia, asystole, hypotension, bronchospasm, and hypersalivation. Close observation and monitoring with telemetry in a controlled setting are warranted. In a double-blind, randomized placebo-controlled trial of 21 patients with a cecal diameter of at least 10 cm, despite 24 hours of conservative therapy, 10 out of 11 patients randomized to receive an infusion of

2 mg neostigmine had prompt colonic decompression, and one responded after subsequent retreatment.³⁶ None of the 10 patients randomized to placebo experienced resolution, but all 7 in whom neostigmine was openly administered subsequently responded. In a double-blind, placebo-controlled prospective study in critically ill ventilated patients with CIRCI, continuous infusion of neostigmine at 0.4 to 0.8 mg/h resulted in defecation in 80% of the patients, with no reported adverse events.³ Contraindications to the use of neostigmine include mechanical obstruction, the presence of ischemia or perforation, pregnancy, uncontrolled cardiac arrhythmias, severe active bronchospasm, and renal insufficiency.^{2,3} Unfortunately, relapse of Ogilvie's syndrome after the initial response to medical therapy occurs in 40% of patients, and more invasive therapies may then be required.³⁷

Surgical Management

Once medical management has failed, endoscopic decompression is the initial invasive procedure of choice for patients with marked cecal distention (>10 cm) of significant duration (>3–4 days), not improving after 24 to 48 hours of supportive therapy, and who have contraindications to or fail neostigmine treatment.⁴ Colonoscopy is performed without bowel preparation, thus further complicating the procedure. Liberal use of air insufflation should be avoided as it may lead to perforation. Advancing the scope to the level of the proximal hepatic flexure is usually sufficient to obtain adequate decompression.⁷ Gas should be aspirated and the viability of the mucosa assessed during slow withdrawal of the scope. If signs of ischemia are present, the procedure should be aborted. Successful decompression has been achieved in 70% to 80% of patients; however, the recurrence rates are as high as 50%.^{2,38} To increase the therapeutic benefit, decompression tube placement at the time of colonoscopy may reduce recurrence, but controlled trials with this intervention are not available.

Surgical management is rarely necessary and should be reserved for patients who have failed pharmacologic and endoscopic management or those who have clinical signs of colonic ischemia or perforation. Surgical options include a venting stoma (cecostomy) or colectomy. Ogilvie's syndrome is one of the few conditions where cecostomy is indicated. Tube cecostomy should only be performed in patients without evidence of ischemia or perforation. It can be performed laparoscopically or through a limited right lower quadrant incision. A large Foley catheter is left in place for 2 to 3 weeks to allow venting of the colon. Cecostomy can be performed under local anesthesia. In cases of ischemia or perforation, laparotomy is indicated. Segmental or subtotal resection may be performed as dictated by the extent of colon involvement. In the event that a colectomy is needed, an end stoma and mucous fistula should be performed and anastomosis avoided.

Toxic Megacolon

Medical Management

The initial goal of treatment is to reduce the severity of colitis so as to restore normal colonic motility and decrease the likelihood of perforation.²⁵ Patients should be monitored closely in an ICU, with frequent examinations to assess for clinical deterioration. A surgical consultation should be obtained on admission, although medical treatment is successful in about 50% of patients. Initially, complete blood counts, electrolyte panels, and serial plain abdominal films should be reviewed every 12 hours until clinical improvement has been observed. Conditions impairing colonic motility must be corrected (Box 101-1). In general, patients will require adequate resuscitation, electrolyte and vitamin replacement, early optimization of circulation, and, if necessary, mechanical ventilation. A nasogastric tube should be placed to decompress the GI tract. Early total parenteral nutrition has shown no survival benefit and should be reserved for patients who have evidence of severe malnutrition in the absence of bacteremia, especially if they are likely to undergo surgery. However, enteral nutrition should be initiated as soon as possible and tolerance closely monitored. Antimotility agents should be discontinued, and antiperistaltic agents for diarrhea are absolutely contraindicated.

Systemic antibiotics, administered empirically, are necessary to reduce septic complications and peritonitis. Empirical antibiotics should cover both gram-negative and anaerobic species, as guided by local susceptibility patterns and fecal surveillance cultures. It is important to select antibiotics that least inhibit the indigenous colonic flora, and in the case of *C. difficile*, the offending antibiotic should be discontinued. Deescalation of antibiotics should ensue, without delay, once the final microbiological data are obtained.

Patients with toxic megacolon caused by IBD should be treated with high-dose intravenous corticosteroids. Steroid treatment should be started immediately and should not be delayed pending microbiological results. Most authors recommend hydrocortisone 100 mg or equivalent every 6 hours or by continuous infusion. Steroid use should be reevaluated on a regular basis and discontinued once an exclusively infectious etiology of toxic megacolon has been established.

In patients with toxic megacolon due to severe *C. difficile* colitis, the first step is to stop the offending antibiotic and to give vancomycin 125 mg orally, four times a day.³² Treatment should not be delayed while awaiting microbiological confirmation of CDI. Findings suggestive of severe, complicated CDI include admission to ICU, hypotension with or without required use of vasopressors, fever $\geq 38.5^{\circ}\text{C}$, mental status changes, white blood cell count $\geq 35,000$ or <2000 cells/mm³, serum lactate levels >2.2 mmol/L, or evidence of end organ failure. If any of these findings are present, the vancomycin dosing should be increased to 500 mg orally four times a day with the addition of metronidazole 500 mg intravenously every 8 hours. Vancomycin retention enemas (vancomycin 500 mg in 500 mL saline per rectum four times a day) should also be administered.³²

Surgical Management

Patients unresponsive to medical treatment should undergo prompt surgical resection. Surgical intervention should be considered if a patient has progressive signs of organ failure despite optimal medical therapy, CT scan findings suggestive of worsening disease, or signs of peritonitis or perforation. However, because of the lack of prospective randomized studies, it is difficult to identify the optimal point for surgical intervention in patients with severe, fulminant CDI, and the mortality rate ranges from 35% to 80%.³⁹ Subtotal colectomy with end ileostomy is considered the procedure of choice when urgent or emergent surgery is required. More recently, Neal et al. published their experience with an alternative surgical approach comprising diverting loop ileostomy and colonic lavage.⁴⁰ In this technique, an ileostomy is created and intraoperative colonic lavage is performed with a warmed polyethylene glycol solution via the ileostomy. Postoperatively, the patients received antegrade vancomycin flushes (500 mg in 500 mL lactated Ringer's solution) every 8 hours for 10 days. Mortality was reduced from 50% to 19% among the patients treated using this novel technique. There is not currently enough data to support the routine use of this procedure; however, it remains an alternative approach for the treatment of fulminant *C. difficile* colitis.

SUMMARY

Ogilvie's syndrome manifests with massive dilation of the colon in the absence of mechanical obstruction. Evaluation involves exclusion of mechanical obstruction, cessation of offending agents, and selective use of neostigmine and colonic decompression. With appropriate management, colonic pseudo-obstruction usually resolves within several days. Toxic megacolon is a diagnosis based on clinical signs of systemic toxicity in combination with radiographic evidence of colonic dilation. The goal of treatment is to reduce the effects of colonic inflammation and prevent perforation. Timely treatment with broad-spectrum antibiotics combined with cessation of the causative agents helps to minimize the morbidity associated with this disease process. Surgery should be reserved for those patients who fail to respond to medical management or show signs of ischemia or perforation. A high index of suspicion and early recognition of both Ogilvie's syndrome and toxic megacolon are crucial to optimal management.

KEY POINTS

1. Ogilvie's syndrome, or acute colonic pseudo-obstruction, is a syndrome of massive colonic dilation in the absence of mechanical obstruction that develops in critically ill patients with serious underlying medical and surgical conditions.
2. Conservative therapy is the initial preferred management.
3. Numerous contributory metabolic, infectious, and pharmacologic factors are associated with Ogilvie's syndrome. These factors should be identified and corrected early on in treatment.
4. Neostigmine is effective in the majority of cases of Ogilvie's syndrome. Colonic decompression may be required.
5. Toxic megacolon is a syndrome of nonobstructive colonic dilation associated with systemic toxicity.
6. Empiric antibiotics with gram-negative and anaerobic coverage should be initiated early on in the course of treatment.
7. Surgical intervention should be reserved for those patients who fail optimal medical management or show clinical signs of colonic ischemia or perforation.

Five percent to 15% of patients in intensive care units (ICUs) experience acute deterioration in renal function.^{1,2} Renal dysfunction substantially adds to the morbidity and mortality of critically ill patients. Moreover, changes in renal function directly affect drug disposition. Thus, a means to assess renal function is essential for optimal management of patients with critical illness. This chapter reviews selected aspects of renal physiology with an emphasis on measurement of renal function, consequences of altered function, and approaches to improving renal function. The focus is on measurement and optimization of glomerular filtration rate (GFR) and renal blood flow (RBF).

RENAL BLOOD FLOW

Under physiologic conditions, blood flow to the kidneys is 20% of the cardiac output. This high rate of blood flow (1-1.2 L/min) is particularly remarkable because the kidneys make up only 0.5% of the total body weight. The high blood flow rate is due to, at least in part, the unique anatomic arrangement of the renal vasculature, with the interlobar and arcuate vessels offering little resistance to flow. This is because the interlobular arteries originate from the arcuates in a parallel arrangement and because the afferent arterioles also arise in a parallel arrangement from the interlobular vessels. It is this parallel arrangement that accounts for the low resistance in the RBF because the total resistance of n equals parallel paths, each with a resistance R , is R/n^3 . Major resistance vessels in the kidney are the afferent and efferent arterioles that bind the glomerular capillary network. Although total resistance is a function of resistance across each of these vessels, it is a unique feature of the kidney that variations in individual resistances across the afferent and efferent arterioles may lead to alterations in glomerular capillary pressure and, hence, the GFR.³

Despite a wide range of perfusion pressures, under most conditions, the RBF and GFR are relatively constant, a process described as autoregulation. The term *autoregulation* generally refers to the relative constancy of the GFR over a range of perfusion pressures and to the regulation of RBF. Emphasis has been placed on the preglomerular vasculature, mainly the afferent arterioles, as the major site at which renal perfusion is regulated. However, studies also suggest that the larger vessels, such as the interlobular vessels, respond to a variety of vasoactive stimuli and participate in an autoregulatory phenomenon. A variety of hypotheses have been generated to explain the autoregulatory response of the kidney with respect to the RBF. There is evidence to suggest that neural, humoral, or intrarenal factors are involved in the regulation of renal circulation.⁴

The renin-angiotensin pathway has a significant effect on renal hemodynamics. Renin, which is elaborated in the juxtaglomerular cells, is released in response to a decrease in renal perfusion pressure and to altered sodium chloride delivery to the ascending limb and macula densa cells. Increased renin secretion leads to augmented angiotensin II (AII) formation at the local nephron level. AII affects renal vascular resistance through modulation of both afferent and efferent arterioles, with the major effect being on the efferent arterioles.

Renal eicosanoids affect renal hemodynamics. Eicosanoids are biologically active fatty acid products of arachidonic acid and are

synthesized in the kidney in response to a variety of stimuli, with local release and effect on the renal vasculature. Stimulation of the cyclooxygenase pathway and prostaglandin synthetases leads to the formation of endoperoxides (PGG₂ or PGH₂), prostaglandins (PGD₂, PGE₂, PGF_{2α}, or PGI₂), and thromboxane A₂ (TXA₂). Leukotrienes are synthesized through a pathway involving the enzyme lipoxygenase. In the kidney, the major products of arachidonic acid metabolism are PGE₂ and PGI₂ and, to a lesser extent, PGI_{2α}. These compounds have a predominant effect of relaxing renal vascular smooth muscle and lead to vasodilatation, whereas TXA₂ is a vasoconstrictor prostanoid. It is believed that in disease states, endogenous vasodilator prostaglandins have a protective function to maintain renal perfusion and the GFR in response to vasoconstrictor stimuli, including AII and enhanced sympathetic nervous system activity. In contrast, release of vasodilatory prostaglandins is inhibited by nonsteroidal antiinflammatory drugs.

Other vasoactive compounds that affect renal circulation include plasma and glandular kallikreins and kinins and endothelium-derived vasoactive factors, such as nitric oxide and endothelin.⁴ Among the catecholamines, α - and β -adrenergic agonists are known to affect renal vascular tone by causing vasoconstriction and vasodilatation, respectively. In addition, dopamine in low doses leads to renal vasodilatation. Atrial natriuretic peptide and purinergic agents, such as adenosine, also been shown to participate in modulating renal circulation.

The effect of vasoactive mediators on renal circulation is likely to be influenced by changes in salt intake and extracellular fluid (ECF) volume as well as by hydration status. For example, the influence of AII on renal hemodynamics is greater in sodium depletion, which activates the sympathetic nervous system. In response to mild nonhypotensive hemorrhage, renal hemodynamics is relatively well maintained. However, with further reductions in volume associated with more severe hemorrhage, renal ischemia mediated by activation of the renin-angiotensin system, renal efferent adrenergic nerves, and circulating catecholamines may occur.⁴

Modification of dietary protein and amino acid intake may affect renal hemodynamics. Dietary protein intake in excess of 1 g/kg/d has been associated with renal vasodilatation, as have infusions of casein hydrolysates and amino acids.^{5,6} Conversely, chronic consumption of a low-protein diet may be associated with renal vasoconstriction.

Measurement of Renal Blood Flow

The RBF is measured conventionally by the clearance of infused para-aminohippurate (PAH), which is cleared almost totally from the arterial plasma by both filtration and secretion. Thus, its clearance approximates the rate of renal plasma flow (RPF):

$$RPF = U_{PAH} \cdot V / P_{PAH}$$

where U_{PAH} and P_{PAH} refer to urine and plasma PAH concentration, respectively, and V is the urine flow rate in milliliters per minute.

The RBF can be estimated by correction for hematocrit (Hct):

$$RBF = RPF / [1 - Hct]$$

Although available, this test is rarely used in clinical practice. In fact, direct quantitation of the RPF and RBF is rarely indicated outside research studies; however, sometimes it is necessary to document that the kidneys are being perfused. In this case, one of three additional methods may be utilized: (1) selective arteriography, including CT angiography and MR angiography, (2) Doppler ultrasonography, and (3) external radionuclide scanning. Because the latter two methods are noninvasive, they are preferred. With respect to the nuclide study, until recently, scanning was usually performed utilizing ^{125}I -iodohippurate sodium; however, the poor radiologic characteristics of ^{131}I limit its use in renal imaging.⁷ More recent evidence suggests that other agents, such as ^{127}I -orthoiodohippurate and $^{99\text{m}}\text{Tc}$ -L,L-ethylenedicycysteine are superior to ^{125}I -iodohippurate sodium.^{7,8}

Clinical Correlates

Although a significant amount of data has been obtained to indicate a complex relationship between neurocirculatory factors and renal hemodynamics, several points can be made from a clinical perspective. Optimization of cardiac output and ECF volume, including the intravascular space, is essential for the maintenance of renal perfusion. In particular, because the effects of vasoactive compounds such as AII and catecholamines are accentuated in the presence of renal hypoperfusion and volume contraction, attention should be given to the assessment of ECF volume, with correction of any deficits, and to optimize cardiac function. Frequently, pharmacologic agents have been employed to maintain renal perfusion in situations in which this may be compromised. Specifically, there has been widespread use of the so-called low-dose or renal-dose dopamine infusions. This is based on the observation that in low doses ($<3 \mu\text{g/kg/min}$), dopamine leads to renal vasodilatation.⁹ At higher doses, renal vasoconstriction may occur.

The beneficial effects of dopamine infusion have not been documented in patients who exhibit evidence of intravascular volume depletion, and the use of dopamine has been shown to be ineffective beyond a short period of infusion.⁹⁻¹¹ Thus, while infusions of renal-dose dopamine for 24 to 36 hours may be beneficial under the appropriate circumstance, there is no evidence supporting the long-term use of this agent. Furthermore, reports suggest that adverse outcomes are associated with the use of dopamine.¹¹ Continuous infusions of fenoldopam mesylate, a potent dopamine A-1 receptor agonist, have been employed in an attempt to preserve renal function in a variety of clinical settings. A meta-analysis of 16 randomized trials in critically ill patients showed that fenoldopam significantly reduced the risk of acute kidney injury, need for renal replacement therapy, and in-hospital death.¹²

Beyond anecdotal evidence, there are no compelling data to support the use of other potential vasodilator substances such as prostaglandins. Although high-protein feeding and amino acid infusions may increase the RBF by undefined mechanisms, there is no justification in utilizing these therapies solely from a hemodynamic point of view.^{5,6}

■ GLOMERULAR FILTRATION RATE

Of the 500 to 700 mL of plasma delivered per minute to the kidneys (corresponding to an RBF of 1-1.2 L/min), 20% to 25% is filtered. Glomerular filtration is a major function of the kidney and averages approximately 130 mL/min/1.73 m² in normal males and 120 mL/min/1.73 m² in normal females. Estimation or direct assessment of the GFR remains one of the most important measurements of renal function and is widely utilized in clinical practice.

Measurement of Glomerular Filtration Rate

The GFR is classically measured as the clearance of inulin (C_{in}), a fructose polymer with a mean molecular weight of approximately 5 kD. Because this substance is not present endogenously, it must be

given by constant infusion after a loading dose. Inulin is available commercially but is expensive, often difficult to obtain, and cumbersome to utilize. As a result, the C_{in} is rarely used in clinical practice except for research protocols. Although the C_{in} is generally measured chemically, ^3H - and ^{14}C -labeled inulins are also available but are expensive.

Other radiolabeled nuclides have been found to be satisfactory substitutes for inulin and have advantages in the measurement of GFR.^{7,8,13,14} In particular, $^{99\text{m}}\text{Tc}$ -labeled diethylenetriamine pentaacetic acid (DTPA) and ^{125}I - or ^{131}I -labeled iothalamate clearances closely approximate C_{in} .^{15,16} $^{99\text{m}}\text{Tc}$ -DTPA has been utilized and found to give values that correlate closely with the C_{in} in ICU patients.^{17,18} In addition, the clearance of gentamicin has been utilized in a limited fashion to measure GFR.^{19,20} At the present time, it is not common for the GFR to be measured directly. Rather, the GFR is estimated by endogenous creatinine clearance (C_{Cr}) or serum creatinine determination (see later discussion).

The normal values for the GFR obtained previously apply for individuals from teenage years through approximately 35 years. Thereafter, the GFR declines in most individuals. Although this decline was formerly thought to occur at a relatively constant rate of approximately 10 mL/min per decade,²¹⁻²³ more recent data obtained in a longitudinal manner indicate that this reduction is not so predictable.²⁴ In addition, a circadian rhythm for GFR has been described.^{25,26} GFR is maximal in the day, whereas a minimal value during the night has been found in normal individuals. It is not known whether this circadian pattern of GFR occurs in critically ill hospitalized patients.

CREATININE CLEARANCE AND SERUM CREATININE

Creatinine Clearance

The C_{Cr} enjoys widespread use as a reasonable gauge of GFR when great precision is not demanded, which it rarely is in clinical practice. The use of creatinine as a marker of the GFR has the advantage that creatinine is endogenously produced and easily measured by inexpensive methods. Creatinine, like inulin, is freely filtered and absorbed minimally if at all by the tubules. However, creatinine is secreted, and the contribution of secretion to total excretion is greater as the GFR decreases and serum creatinine rises. At GFRs below 40 mL/min, the C_{Cr} exceeds the C_{in} by 50% to 100%.^{15,27} When GFR is significantly depressed and it is deemed important to get a more precise measurement of GFR, one of the previously mentioned methods to estimate the GFR directly might be utilized. Additionally, because the C_{Cr} overestimates the GFR and the clearance of urea underestimates the GFR, the mean value of simultaneously obtained creatinine and urea clearances has been shown to provide a close estimation of the C_{in} when the latter is below 20 mL/min.²⁸

Because cimetidine competes with creatinine for tubular secretion (see later), administration of cimetidine may increase the accuracy of both creatinine clearance in 24-hour collections (when given for several days beforehand) and 4-hour, water-loaded clearances.²⁹⁻³¹ Taking advantage of this effect results in a more accurate estimate of the GFR. Specifically, the C_{Cr} obtained in the presence of cimetidine (400 mg as a priming dose followed by 200 mg every 3 hours) yielded values that closely approximate C_{in} .^{29,30} Volume expansion in humans causes a small rise in the GFR, whereas volume depletion, severe heart failure, hypotension, anesthesia, surgery, trauma, sepsis, and even mild intestinal bleeding without frank hypotension may depress the GFR substantially.

Various methods are available to measure creatinine. Creatinine is frequently measured using the Jaffé alkaline picric acid reaction. Although this method is widely utilized, this reaction also measures other chromogens, which may lead to a false elevation in the estimated serum creatinine (S_{Cr}) measurement. Substances such as acetoacetate (in ketoacidosis), pyruvate, ascorbate, 5-fluorcytosine, certain (but not

all) cephalosporin antibiotics, and very high urate artifactually raise S_{Cr} in normal subjects by 0.5 to 2 mg/dL.³²⁻³⁸ These substances are excreted into the urine but contribute trivially compared with overall urine creatinine (U_{Cr}). Thus, noncreatinine chromogens affect the S_{Cr} but have little effect on the U_{Cr} .

In individuals with normal renal function, the contribution of serum noncreatinine chromogens in raising the S_{Cr} is approximately equal to the contribution of secretion to creatinine excretion, such that the C_{Cr} closely approximates the GFR. As the GFR decreases, the contribution of noncreatinine chromogens to the total measured S_{Cr} becomes less than the secreted moiety, and the C_{Cr} overestimates GFR to a greater extent. Direct enzymatic creatinine measurements are not affected by noncreatinine chromogens. Very high levels of serum glucose (>1000 mg/dL) and 5-flucytosine may interfere with the enzymatic reaction, whereas high levels of bilirubin (>5 mg/dL) affect the autoanalyzer method³⁶ and lead to falsely low S_{Cr} values. It is therefore important to know the method by which a given laboratory measures S_{Cr} . Competing for the same proximal tubular organic base secretory site as creatinine, certain pharmacologic agents may suppress this process and lead to a rise in the S_{Cr} . Trimethoprim, probenecid, and cimetidine, but not ranitidine, are organic bases that inhibit creatinine secretion competitively and can result in a mild elevation in the S_{Cr} , usually 0.5 mg/dL or less.³⁹⁻⁴²

As with all clearance methods, the C_{Cr} is subject to errors that may amount to as much as 10% to 15%. In addition to potential problems in estimating the S_{Cr} and U_{Cr} , errors in timing of urine collection, incomplete collection, and inaccurate measurement of urine volume are other factors that contribute to errors.⁴³ Although 24-hour U_{Cr} clearances have been widely utilized, no specified time period is required for the clearance to be obtained. In fact, shorter collection periods of several hours may be more accurate in patients passing adequate amounts of urine (not oliguric), particularly if the patient is not in a steady state (see later). To reduce errors in volume measurement, one can induce water diuresis in stable subjects before beginning the test,⁴⁴ although this is rarely practical in the ICU setting. Nevertheless, because many ICU patients have indwelling Foley catheters, it should be possible for accurately timed urine collections to be obtained and for the C_{Cr} to be measured with reasonable accuracy.

Serum Creatinine

Because of the practical and technical problems in obtaining estimates of the GFR by clearance methods, renal function is most commonly estimated by following the S_{Cr} in hospitalized patients. Creatinine is formed nonenzymatically from creatine and phosphocreatine in muscle cells and is normally present in the serum at a concentration of 0.8 to 1.4 mg/dL in adults and 0.3 to 0.6 mg/dL in children and pregnant subjects. The measured S_{Cr} depends on the method of measurement, as discussed previously, the GFR, rate of creatinine production, volume of distribution (e.g., S_{Cr} is lower in anasarca), and extent of its tubular secretion and intestinal degradation.³ Because creatinine production is closely related to muscle mass, the S_{Cr} is generally less in females than in males and decreases as muscle mass is lost with aging or debilitating illnesses.

The relationship between the S_{Cr} and C_{Cr} (and hence GFR) can be described by a rectangular hyperbola⁴⁵; however, this relationship applies in the steady state and assumes a constant rate of creatinine production (Fig. 102-1). Thus, a doubling of the S_{Cr} reflects a 50% decrease in C_{Cr} , a four-fold increase in the S_{Cr} , a 75% drop in the GFR, and so on. Because creatinine production may not remain constant, the S_{Cr} may underestimate the decrease in GFR in critically ill patients who have a decrease in muscle mass secondary to an ongoing catabolic state. Moreover, it should be appreciated that the S_{Cr} is an insensitive marker of change early in the course of renal disease. Thus, a 33% fall in the GFR may raise the S_{Cr} from 0.8 to 1.2 mg/dL, a value still within the normal range. If the prior value is not known, this fall in the GFR may go unrecognized.

FIGURE 102-1 ■ Relationship between creatinine clearance and serum creatinine. In steady state, serum creatinine should increase twofold for each 50% reduction in creatinine clearance. Inset represents enlarged view of changes in serum creatinine as creatinine clearance decreases from 120 to 60 mL/min. If serum creatinine is 0.8 mg/dL when creatinine clearance is 120 mL/min, creatinine clearance can decrease by 33% such that increased serum creatinine is still within normal range.

The S_{Cr} provides a close estimate of the GFR only in the steady state. With an abrupt decrease in the GFR, as may occur in acute renal failure, creatinine production would be expected to continue unchanged, but because of the decrease in the GFR, creatinine excretion will be impaired. As a result, the S_{Cr} increases until a new steady state is obtained, at which time the amount of creatinine produced equals the amount filtered ($GFR - S_{Cr}$) and excreted ($U_{Cr} - V$). Depending on the extent of damage and decrease in the GFR, it may take several days for a new steady state to be achieved. Therefore, following an insult leading to an abrupt decrease in the GFR, the S_{Cr} rises progressively over the next several days. This should not be interpreted as a new insult each day but rather that a steady state has not yet been obtained. While the S_{Cr} is changing, its absolute value cannot be used as an accurate measure of the decrease in the GFR. If an accurate measurement of the GFR is needed during this time, a short C_{Cr} can be obtained.

Many equations have been developed to estimate the C_{Cr} based on the S_{Cr} without collection of urine.^{45,46} Box 102-1 is a compilation of the more commonly used equations.⁴⁷ These equations generally take into consideration muscle mass (estimated as body weight), sex (males having a higher GFR than females), and age. Aging, hepatic diseases, excessive muscle wasting, severe muscular atrophy or dystrophy, hyperthyroidism, paralysis, and chronic glucocorticoid therapy are associated with reduced creatinine generation.¹⁷ In addition, particularly at low levels of GFR, correction for nonrenal creatinine metabolism is recommended.^{48,49} One of the most commonly utilized equations is that developed by Cockcroft and Gault⁵⁰:

$$C_{Cr} = \frac{(140 - \text{age}) \cdot \text{lean wt in kg}}{72 \cdot S_{Cr}}$$

where age is expressed in years. The preceding expression is used for men. The formula for women is the preceding formula multiplied by 0.85.

BOX 102-1

Common Equations for Estimating Glomerular Filtration Rate or Creatinine Clearance

COCKCROFT-GAULT (C_{Cr} • BSA/1.73 m²)For men: $C_{Cr} = [(140 - \text{age}) \cdot \text{weight (kg)}] / S_{Cr} \cdot 72$ For women: $C_{Cr} = [(140 - \text{age}) \cdot \text{weight (kg)}] / S_{Cr} \cdot 72 \cdot 0.85$ **MDRD (1)** $GFR = 170 \cdot [S_{Cr}]^{-0.999} \cdot [\text{age}]^{-0.176} \cdot [0.762 \text{ if patient is female}] \cdot [1.18 \text{ if patient is black}] \cdot [BUN]^{-0.170} \cdot [Alb]^{0.318}$ **MDRD (2)** $GFR = 186 \cdot [S_{Cr}]^{-1.154} \cdot [\text{age}]^{-0.203} \cdot [0.742 \text{ if patient is female}] \cdot [1.212 \text{ if patient is black}]$ **JELLIFE (1) (C_{Cr} • BSA/1.73 m²)**For men: $(98 - [0.8 \cdot (\text{age} - 20)]) / S_{Cr}$ For women: $(98 - [0.8 \cdot (\text{age} - 20)]) / S_{Cr} \cdot 0.90$ **JELLIFE (2)**For men: $(100 / S_{Cr}) - 12$ For women: $(80 / S_{Cr}) - 7$ **MAWER**For men: $\text{weight} \cdot [29.3 - (0.203 \cdot \text{age})] \cdot [1 - (0.03 \cdot S_{Cr})]$ For women: $\text{weight} \cdot [25.3 - (0.175 \cdot \text{age})] \cdot [1 - (0.03 \cdot S_{Cr})]$ **BJORNSSON**For men: $[27 - (0.173 \cdot \text{age})] \cdot \text{weight} \cdot 0 / S_{Cr}$ For women: $[25 - (0.175 \cdot \text{age})] \cdot \text{weight} \cdot 0.07 / S_{Cr}$ **GATES**For men: $(89.4 \cdot S_{Cr}^{-1.2}) + (55 - \text{age}) \cdot (0.447 \cdot S_{Cr}^{-1.1})$ For women: $(89.4 \cdot S_{Cr}^{-1.2}) + (55 - \text{age}) \cdot (0.447 \cdot S_{Cr}^{-1.1})$ **SALAZAR-CORCORAN**For men: $[137 - \text{age}] \cdot [(0.285 \cdot \text{weight}) + (12.1 \cdot \text{height}^2)] / (51 \cdot S_{Cr})$ For women: $[146 - \text{age}] \cdot [(0.287 \cdot \text{weight}) + (9.74 \cdot \text{height}^2)] / (60 \cdot S_{Cr})$

The reliability of the Cockcroft-Gault equation as a measure of the GFR has been assessed in patients with diabetes, pregnant women with renal disease,⁵¹ obese individuals,⁵² elderly individuals,^{53,54} and African Americans with hypertensive renal disease.⁵⁵ It has also been assessed in critically ill patients.⁵⁶ These studies have indicated that the accuracy of GFR estimates using the Cockcroft-Gault equation is similar to or greater than 24-hour C_{Cr} and that the precision is better. This equation seems to be most accurate for estimating the GFR when the latter is in the range of 10 to 100 mL/min.^{52,55,56} The advantage of this formula is that it is simple and underscores the essential determinants of C_{Cr} .

The Modification of Diet in Renal Disease (MDRD) study equation has gained widespread acceptance by most clinical laboratories, which now routinely report estimated GFRs across populations when serum creatinine testing is ordered.⁵⁷⁻⁵⁹ Its major limitations are imprecision and underestimation of the measured GFR at high GFRs ($GFR > 60 \text{ mL/min/1.73 m}^2$). The MDRD equation is generally more precise than the Cockcroft-Gault equation.⁶⁰

Limitations at higher GFRs prompted a recent modification by the Chronic Kidney Disease Epidemiology Collaboration Research Group.⁶¹ This equation offers improved precision, especially with higher GFRs up to $90 \text{ mL/min/1.73 m}^2$.

CKD-EPI equation for estimated GFR (natural scale):

African Americans:

$$\text{Female } (S_{Cr} \leq 0.7) \text{ GFR} = 166 \cdot (S_{Cr}/0.7)^{-0.329} \cdot (.0993)^{\text{Age}}$$

$$\text{Female } (S_{Cr} > 0.7) \text{ GFR} = 166 \cdot (S_{Cr}/0.7)^{-1.209} \cdot (.0993)^{\text{Age}}$$

$$\text{Male } (S_{Cr} \leq 0.9) \text{ GFR} = 163 \cdot (S_{Cr}/0.9)^{-0.411} \cdot (.0993)^{\text{Age}}$$

$$\text{Male } (S_{Cr} > 0.9) \text{ GFR} = 163 \cdot (S_{Cr}/0.9)^{-1.209} \cdot (.0993)^{\text{Age}}$$

Caucasians or others:

$$\text{Female } (S_{Cr} \leq 0.7) \text{ GFR} = 144 \cdot (S_{Cr}/0.7)^{-0.329} \cdot (.0993)^{\text{Age}}$$

$$\text{Female } (S_{Cr} > 0.7) \text{ GFR} = 144 \cdot (S_{Cr}/0.7)^{-1.209} \cdot (.0993)^{\text{Age}}$$

$$\text{Male } (S_{Cr} \leq 0.9) \text{ GFR} = 141 \cdot (S_{Cr}/0.9)^{-0.411} \cdot (.0993)^{\text{Age}}$$

$$\text{Male } (S_{Cr} > 0.9) \text{ GFR} = 141 \cdot (S_{Cr}/0.9)^{-1.209} \cdot (.0993)^{\text{Age}}$$

Serum Cystatin C

Because of the limitations in utilizing creatinine as a marker for the GFR, there has been an ongoing search for alternative GFR markers. To this end, cystatin C has emerged as a possible candidate biomarker. Cystatin C is a low-molecular-weight protein of 13.3 kDa and is expressed by all nucleated cells. It is cleared by glomerular filtration and metabolized in the kidney. Serum cystatin C levels are minimally affected by demographics such as race and muscle mass. Although initially thought to be an ideal GFR marker, a number of factors may influence cystatin C levels other than GFR. These include hyperthyroidism, malignancy, corticosteroid use, diabetes mellitus, leukocyte count, albumin concentration, and C-reactive protein levels. Despite such limitations, cystatin C use is increasing and analytical methods are standardized. Cystatin C, like creatinine, has been employed in equations that more accurately estimate the GFR. By using both creatinine and cystatin C, even more accuracy in determining the GFR can be obtained, especially in populations with higher baseline levels for GFR. Although the use of these equations has not become routine, cystatin C will likely emerge as an important biomarker for the estimation of GFR.⁶²

Serum Urea Nitrogen

Less accurate as a marker of GFR than the S_{Cr} , serum urea nitrogen (SUN) (or blood urea nitrogen [BUN]) is still used extensively in clinical practice to estimate renal function. Although this was the earliest available indicator of renal function, several other factors should be appreciated regarding the use of this substance. Urea, like creatinine, is freely filtered and is retained in the blood as the GFR falls. However, in contrast to creatinine, urea may be reabsorbed to a significant extent. The excretion of urea tends to be increased with increasing urine flow rates, whereas its excretion is reduced when tubular fluid reabsorption is enhanced. Of greater importance, urea production is more variable than that of creatinine. Produced in the liver, urea increases with high protein intake, amino acid infusions, and hypercatabolic states. In addition, endogenous sources of protein, such as absorbed hemoglobin from gastrointestinal bleeding, may contribute to increased urea synthesis. Even at a constant GFR, SUN may rise in subjects on high protein intake and fall with protein restriction or on refeeding of previously starved, nonhypercatabolic subjects.

Several pharmacologic agents may also affect urea nitrogen formation. Tetracyclines may lead to an increase in SUN by an antianabolic effect without any detectable change in the GFR, whereas glucocorticoids and severe illnesses or trauma do the same by inducing endogenous protein hypercatabolism. Because of the widespread use of hyperalimentation in ICU patients, impairment in renal function is often associated with a marked disproportion in the elevation of SUN compared with S_{Cr} . For this reason, an issue is raised as to whether SUN elevation itself poses an important threat to patients if the GFR is in a range that should not lead to enhanced morbidity by itself. In those circumstances, it is useful to measure the rate of urea appearance (or generation) to estimate whether other factors such as gastrointestinal bleeding, excessive amino acid infusions, and protein administration are contributing to the increase in SUN above that expected by a decrease in the GFR.^{47,48} Urea nitrogen (UN) appearance

can be determined from urine urea nitrogen (UUN), SUN, and body weight as follows:

$$UN = UUN \cdot V + \Delta \text{ body pool UN}$$

where $UUN \cdot V$ is the 24-hour UN excretion, and Δ body pool UN = $0.6 - \text{nonedematous weight (kg)} \cdot \Delta \text{ SUN/day}$.

If the weight is changing^{47,48}:

$$\Delta \text{ body pool UN} = (0.6 \cdot \text{nonedematous weight} \cdot \Delta \text{ SUN}) + (\Delta \text{ weight} \cdot \text{final SUN})$$

Nitrogen balance (BN) is equal to:

$$BN = IN - UN - NUN$$

where IN is the urea nitrogen intake, and NUN is nonurea nitrogen excretions.⁴⁸

NUN, which includes fecal nitrogen, urinary creatinine, uric acid, and unmeasured nitrogen, averages 0.031 g nitrogen/kg/d.⁴⁸ Data obtained from the measurements just described may be quite useful in evaluating the cause of disproportionate elevations in SUN. If a patient is in the steady state (with a stable weight and SUN), $BN = 0$, and IN can be estimated from $UN + NUN$.⁴⁸ Because catabolism, except for severe trauma and burns, is usually 2 to 4 g nitrogen per day, additional conclusions can be drawn if the patient is not in the steady state. For example, if it is known that IN is less than $UN + NUN$, gastrointestinal bleeding with or without excess catabolism would be suggested. Similarly, one can evaluate if an increase in SUN is a reflection of excessive exogenous protein and amino acid administration (usually >1.5 g/kg/d; g UN 0.16 = g protein or amino acids). If the IN is above the UN, such as in severe liver disease, the clinician might more carefully evaluate changes in weight and SUN as well as clearances because the latter may be more severely depressed than initially suspected.

SODIUM BALANCE AND EXTRACELLULAR FLUID VOLUME

Sodium is the primary cation of the ECF, present at a concentration of 140 to 142 mmol/L. The volume of the ECF is approximately 20% of the total body weight and represents one-third of the total body water. Regulation of ECF volume is governed by factors regulating sodium balance and sodium excretion.⁶³

Under physiologic conditions and in the steady state, sodium balance is maintained because the amount of sodium excreted equals that which enters the body by oral and intravenous routes. The excretion of sodium excretion and fraction of filtered sodium that is excreted (FE_{Na}) can be readily determined. Absolute sodium excretion is measured as the product of urine sodium concentration and urine volume:

$$Na^+ \text{ excretion} = (U_{Na} \cdot V)$$

The FE_{Na} can be determined as follows:

$$FE_{Na} = U_{Na} \cdot V / GFR \cdot S_{Na}$$

For practical reasons, the C_{Cr} ($= U_{Cr} \cdot V / S_{Cr}$) is used to estimate the GFR, such that:

$$FE_{Na} = U_{Na} \cdot V / U_{Cr} \cdot V / S_{Cr} \cdot S_{Na}$$

Because V in the numerator and denominator cancels out:

$$FE_{Na} = U_{Na} / S_{Na} \cdot S_{Cr} / U_{Cr}$$

Thus, the FE_{Na} can be calculated from sodium and creatinine determined in a random urine sample and serum (or plasma) simultaneously. The resulting calculation is expressed as a percentage by multiplying by 100. This test is of value in the setting of acute renal failure to aid in distinguishing a prerenal from a renal parenchymal etiology.⁶⁴ It is not usually helpful in aiding in the diagnosis of urinary tract obstruction or in the presence of underlying chronic renal insufficiency. The reason for the difficulty in interpretation in chronic renal insufficiency can be illustrated by the following considerations. At a GFR of 130 mL/min and a dietary sodium intake of 3 g of sodium (130 mmol), an individual in sodium balance will excrete 0.5% of the filtered load ($FE_{Na} = 0.5\%$). For sodium balance to be maintained at lower levels of the GFR with the same sodium intake, the FE_{Na} must be increased progressively. Successive decreases in the GFR by 2 from 130 would result in FE_{Na} of 1%, 2%, 4%, and 8%, respectively. Thus, interpretation of the FE_{Na} in a patient with acute renal failure superimposed on chronic renal insufficiency is problematic unless the prior steady-state FE_{Na} is known, but this is rarely the case.

The fractional excretion of chloride (FE_{Cl}) has been suggested to be more accurate than that of sodium in helping to distinguish prerenal from parenchymal causes of acute renal failure.⁶⁵ This is particularly so in the situation in which acute renal failure occurs with simultaneous metabolic alkalosis. If the urine contains substantial amounts of bicarbonate urinary pH ($U_{pH} > 7$), sodium excretion increases to maintain electroneutrality. Under these circumstances, the FE_{Na} may give misleading information, but the FE_{Cl} can be used to obtain the same information.

Although urinary sodium excretion can be used to help make determinations with respect to the ECF volume under certain circumstances, this may be fraught with potential errors. No laboratory test is available to provide this information. Rather, an astute clinician must rely on bedside evaluation complemented, where appropriate, with measurements of central venous pressure and pulmonary capillary wedge pressure to assist in making determinations with respect to the ECF volume status. For example, a low FE_{Na} (<1%) in the setting of acute renal failure usually indicates a decrease in renal perfusion but does not provide information on the status of the patient's ECF volume. Because a low FE_{Na} can be seen with either ECF volume contraction or severe congestive heart failure, these conditions must be distinguished at the bedside. Moreover, sometimes a low FE_{Na} exists even in the presence of parenchymal renal disease, such as acute glomerulonephritis, severe burns, and radiocontrast nephropathy. Finally, administration of potent diuretic agents can alter the FE_{Na} and may result in misleading interpretations. For this reason, urine samples should be obtained before diuretics are administered. However, it may not be possible to obtain urinary sodium or chloride values while a patient is not receiving diuretics. In this setting, the fractional excretion of urea nitrogen has been employed to distinguish prerenal from renal causes of acute kidney injury. In a well-hydrated individual, the Fe_{UN} is 50% to 65%,⁶⁶ whereas in oliguric prerenal azotemic individual, the Fe_{UN} is below 35%. The use of Fe_{UN} in the setting of acute kidney injury has not attained widespread acceptance owing to variable results in comparative trials.^{66,67}

There is now ample evidence that in a patient in positive sodium balance, diuretic therapy should not be utilized without simultaneously restricting sodium intake, including intravenous saline, if negative sodium balance and reduction in edema fluid are desired.⁶⁸ In general, this requires restriction of dietary sodium intake, usually to less than 2 g of sodium per day (0.88 mmol) if the patient is in an edema-forming state. Although diuresis can be affected even with liberal sodium intake, this requires higher doses of diuretics and more frequent administration of these agents. The coexistence of hyponatremia should not deter clinicians from restricting sodium intake but

rather should cause them to address solute-free water intake as well. Under certain circumstances, obligatory intakes make it difficult to achieve optimal restriction to assist diuresis. That is, with various pharmacologic drips, blood products, and feeding regimens necessary in acutely ill patients in the ICU, restricting sodium intake may become a difficult problem. Under those circumstances, increasing doses of diuretics, including continuous infusions of loop diuretics, may be required.

KEY POINTS

1. Acute deterioration of renal function is common in the ICU and contributes significantly to overall morbidity and mortality.
2. The serum creatinine concentration often underestimates the decrease in GFR and may be abnormal only after marked reductions in GFR.
3. Utilizing equations to estimate renal function should be routine in the ICU.

One of the first large, randomized trials exploring the use of low-dose dopamine (<3 µg/kg/min) and high-dose dopamine in ICU patients. The study revealed that there was no evidence that low-dose dopamine improved survival or obviated the need for dialysis, and its use should be discouraged.

Comprehensive review of the equations used to predict GFR and the presentation of a newly derived equation using large clinical data sets. The CKD-EPI equation is probably the best equation to estimate GFR in the steady state.

Robert S, Zarowitz BJ, Peterson EL, Dumler F. Predictability of creatinine clearance estimates in critically ill patients. *Crit Care Med* 1993;21:1487–1495.

Creatinine clearance, inulin clearance, and estimates of GFR based on the Cockcroft-Gault equation were compared in 20 ICU patients. This study emphasized the inaccuracies of obtaining creatinine

clearances in the ICU setting. The Cockcroft-Gault equation accurately predicted GFR as determined by inulin clearances.

This study in 18 ICU patients compared clearances of inulin, creatinine, and ^{99m}Tc-DTPA to estimated Cockcroft-Gault clearance. The clearance of DTPA correlated best to inulin clearance throughout the entire range of clearances studied. DTPA clearance was also simple and inexpensive to perform in the ICU setting.

INCIDENCE OF ACUTE KIDNEY INJURY IN THE INTENSIVE CARE UNIT

Using the Risk, Injury, Failure, Loss and End-stage Kidney (RIFLE) or Acute Kidney Injury Network (AKIN) criteria, the incidence of acute kidney injury (AKI) in the intensive care unit (ICU) varies from 20% to 67% depending on the study.¹ AKI requiring renal replacement therapy (RRT) in the ICU has a high mortality rate of over 50%. The commonest cause of AKI in the ICU is septic shock. AKI is a significant problem in ICU patients and carries a high mortality rate and long-term morbidity. A major obstacle to the development of improved management strategies for AKI is the absence of sensitive and specific biomarkers of this clinical entity.² Therapeutic measures are sometimes started late in the course of AKI. The optimum time to start RRT in the ICU is unknown.² Therefore, there is a need to redefine what constitutes AKI in the ICU and to develop accurate biomarkers.³

SERUM CREATININE IN AKI

Serum creatinine (SCr) and blood urea nitrogen (BUN) have typically been used to diagnose AKI. Creatinine is generated in muscles from the nonenzymatic conversion of creatine and phosphocreatine. SCr is not sensitive or specific for the diagnosis of AKI. Interference with the creatinine assay using the Jaffe reaction may give false SCr values.⁴ SCr may change due to nonrenal factors independent of kidney function, e.g., age, gender, race, muscle mass, nutritional status, total parenteral nutrition and infection.^{4,5} SCr may also be altered as a result of renal factors that are independent of kidney function. For example, medications such as trimethoprim, cimetidine, and salicylates alter the tubular secretion of creatinine, leading to changes in SCr independent of the glomerular filtration rate (GFR).^{4,5} In addition, SCr is not sensitive to the loss of kidney reserve as evidenced by the small change in SCr after the loss or donation of a kidney with one normal remaining kidney.⁶ Alterations in SCr may lag several days behind actual changes in GFR.^{5,7}

A biomarker that is released into the blood or urine by the injured kidney and is analogous to troponin release by injured myocardial cells after myocardial ischemia or infarction may be a more sensitive and specific marker of AKI than BUN and SCr. In addition, earlier detection of AKI with a kidney-specific biomarker may result in earlier nephrology consultation, more optimal dosing of antibiotics in ICU patients, avoidance of nephrotoxic agents, and even earlier initiation of RRT.⁸

NEUTROPHIL GELATINASE-ASSOCIATED LIPOCALIN

Neutrophil gelatinase-associated lipocalin (NGAL) is a small protein expressed in neutrophils and epithelial cells such as renal tubular epithelial cells. NGAL is a component of innate immunity to bacterial infection and is expressed by immune cells, hepatocytes, and renal tubular cells in various disease states.⁹ NGAL is easily detected in the urine, and NGAL protein increases in the kidney and in the urine after ischemic and cisplatin-induced AKI in rats and mice.^{10,11}

NGAL is the most extensively studied biomarker in AKI¹²⁻¹⁶ (Table 103-1). Based on the studies of NGAL as a biomarker of AKI after cardiac surgery, NGAL has been investigated as an early biomarker of

AKI in the ICU. Urine NGAL is an early biomarker of AKI in critically ill children on mechanical ventilation.¹⁷ In 140 pediatric patients, the mean and peak urine NGAL concentrations increased with worsening maximum RIFLE status. Urine NGAL concentrations rose in AKI and 2 days before and after a 50% or greater rise in SCr. Urine NGAL was a good diagnostic marker for AKI, with an area under the receiver operating characteristic (ROC) curve of 0.78. Urine NGAL was also a marker of the persistence of AKI for 48 hours or longer, with an area under the ROC curve of 0.79. However, urine NGAL was not a good marker for AKI severity when it was recorded after a rise in SCr had occurred. In 88 critically ill adults, serum NGAL had a sensitivity of 85% and a specificity of 97% to predict the development of AKI.¹⁸

A multicenter study of serum NGAL was performed in 143 critically ill children with systemic inflammatory response syndrome (SIRS) or septic shock during the first 24 hours of admission to the pediatric ICU.¹⁹ There was a significant difference in the serum NGAL between healthy children, critically ill children with SIRS, and critically ill children with septic shock. Serum NGAL was significantly increased in critically ill children with AKI compared with those without AKI. Thus, serum NGAL is a highly sensitive but nonspecific predictor of AKI in critically ill children with septic shock.

The ability of plasma NGAL (pNGAL) to predict AKI in adult ICU patients was confirmed in another study.²⁰ Using a cut-off of 155 nmol/L, the sensitivity and specificity of pNGAL to predict AKI were 82% and 97%, respectively (area under the ROC curve = 0.92). Of the patients who required RRT, all of them had pNGAL of more than 303 nmol/L. The study concluded that pNGAL at ICU admission was an early biomarker of AKI in adult ICU patients. pNGAL increased 48 hours before RIFLE criteria were observed.²⁰

In another study of pNGAL in the ICU, the influence of sepsis on NGAL was determined. Sixty-five patients admitted to a general ICU with normal SCr were studied.²¹ Data from 27 patients with SIRS, severe sepsis or septic shock without AKI and 18 patients with septic shock and concomitant AKI were analyzed. Peak levels of pNGAL were not significantly different between septic shock patients with and without AKI. Urine NGAL was a good predictor (area under the ROC curve = 0.86), whereas pNGAL was a poor predictor (area under the ROC curve = 0.67) of AKI within the next 12 hours in patients with septic shock. The authors concluded that pNGAL is raised in patients with SIRS, severe sepsis, and septic shock and should be used with caution as a marker of AKI in ICU patients with septic shock. Urine NGAL was more useful for predicting AKI, as the levels were not elevated in septic shock patients without AKI.

The predictive value of urine NGAL, pNGAL, and plasma cystatin C to differentiate among sustained, transient, and absent AKI was compared in 700 ICU patients in a prospective cohort study.²² Urine NGAL was the only biomarker that could significantly differentiate sustained from transient AKI on ICU admission. Urine NGAL performed better than cystatin C for the prediction of sustained AKI. The study concluded that urine NGAL measured on ICU admission can be used to differentiate patients with sustained AKI from patients with transient AKI or without AKI. Combining biomarkers such as pNGAL, urine NGAL, and plasma cystatin C with clinical characteristics adds some value to the predictive model.

In a prospective study of serum NGAL as an outcome-specific biomarker in critically ill patients at the initiation of RRT,²³ serum NGAL was measured in 109 critically ill patients with AKI at the

TABLE 103-1 NGAL as a Biomarker of AKI in the ICU

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |
|-----------------------|-----|--|--------------------------|-----|
| Adults | 632 | NGAL measured at ICU admission predicted the development of severe AKI, similar to serum creatinine-derived eGFR. | 0.77-0.88 | 26 |
| Adults | 301 | Plasma NGAL was a good diagnostic marker for AKI development and for RRT use. | 0.78-0.82 | 24 |
| Adults | 109 | NGAL was higher in non-survivors than in survivors. Serum NGAL was a strong independent predictor for 28-day survival. | ND | 23 |
| Adults | 700 | Urine NGAL performed better than cystatin C for the prediction of sustained AKI. | ND | 22 |
| Adults | 88 | Urine NGAL was more useful than serum NGAL in predicting AKI. Urine NGAL levels were not elevated in septic patients without AKI. | 0.86 | 21 |
| Adults | 65 | NGAL at ICU admission was an early biomarker of AKI. | 0.96 | 20 |
| Adults | 88 | Plasma NGAL at ICU admission was an early biomarker of AKI. Plasma NGAL increased 48 hours before RIFLE criteria. | 0.92 | 20 |
| Children | 140 | Urine NGAL increased in AKI patients 2 days before a 50% or greater rise in serum creatinine. | 0.78 | 17 |
| Children | 168 | Serum NGAL increased in AKI patients compared with that in patients without AKI. | | 19 |
| Adults | 88 | Serum NGAL predicted the development of AKI. | 0.96 | 18 |
| Children with sepsis | 143 | A significant difference was found in the serum NGAL between healthy children, critically ill children with SIRS, and critically ill children with septic shock. | | 19 |
| Emergency department | 635 | Elevated urine NGAL in AKI patients was compared to prerenal azotemia, CKD, or normal kidney function. Urine NGAL was highly predictive of clinical outcomes. | 0.948 | 91 |
| Critically ill/Trauma | 31 | Urinary NGAL was a predictor of AKI. | 0.98 | 92 |

AKI, acute kidney injury; CKD, chronic kidney disease; CPB, cardiopulmonary bypass; eGFR, estimated glomerular filtration rate; ND, not determined; NGAL, neutrophil gelatinase-associated lipocalin; RRT, renal replacement therapy; SCr, serum creatinine; SIRS systemic inflammatory response syndrome.

initiation of RRT. There was a significant difference in the serum NGAL between healthy subjects, critically ill patients with SIRS, and critically ill patients with sepsis. Multiple linear regression showed that NGAL levels were independently related to the severity of AKI and the extent of systemic inflammation. NGAL levels were higher in nonsurvivors compared with those in survivors. Serum NGAL was a strong independent predictor for 28-day survival.

The diagnostic accuracy of pNGAL for the early detection of AKI and the need for RRT in an adult ICU was examined in a study of 307 consecutive adult patients admitted to a general medical/surgical ICU.²⁴ pNGAL was a good diagnostic marker for AKI development within the next 48 h (area under the ROC curve = 0.78) and for RRT use (area under the ROC curve = 0.82). Peak pNGAL concentrations increased with worsening AKI severity.

In a prospective observational study, 106 ICU patients were included to determine whether a panel of novel and traditional renal markers is superior to conventional renal markers in predicting RRT requirements.²⁵ Urine NGAL, serum cystatin C, and Acute Physiology and Chronic Health Evaluation (APACHE) II score were significant independent predictors of RRT (urine NGAL: area under the ROC curve = 0.73, serum cystatin C: area under the ROC curve = 0.76, SCr: area under the ROC curve = 0.78, APACHE: area under the ROC curve = 0.73). SCr combined with normalized NGAL and serum cystatin C combined with NGAL were the best predictors for RRT initiation (area under the ROC curve = 0.8). The combination of serum cystatin C and APACHE II score proved to be the best for detecting patients without AKI on ICU entry (area under the ROC curve = 0.78). The study concluded that the combination of a marker of GFR with one of tubular injury was the best predictor of RRT.

The ability of pNGAL and urine NGAL compared with estimated GFR (eGFR) to predict severe AKI was determined in a study of 632 patients on ICU admission.²⁶ The primary outcome measure was the occurrence of AKI based on the RIFLE classification during the first week of ICU stay. pNGAL and urine NGAL values at ICU admission were significantly related to AKI severity. The areas under the ROC curves for pNGAL and urine NGAL were RIFLE category—risk (RIFLE R; 0.77 and 0.80, respectively), RIFLE category—injury (RIFLE I; 0.80 and 0.85, respectively), and RIFLE category—failure (RIFLE F;

0.86 and 0.88, respectively) and were comparable with those of admission eGFR (0.84, 0.87, and 0.92, respectively). Thus, NGAL measured at ICU admission predicts the development of severe AKI similar to SCr-derived eGFR. It was also found that NGAL in combination with eGFR alone or with other clinical parameters has increased predictive ability.

In summary, NGAL appears to be an excellent biomarker of AKI and the need for RRT in some studies. However, there is variation among studies, and conditions such as sepsis, chronic obstructive pulmonary disease (COPD), cardiac dysfunction, age (NGAL seems superior in children), sex, and baseline renal function may affect the sensitivity and specificity of NGAL as a biomarker of AKI in the ICU.²⁷ Thus, there are limits in the interpretation of NGAL in AKI, and NGAL may be increased in sepsis without AKI.²⁸ pNGAL is a marker of severity in patients with severe acute pancreatitis without AKI and may predict the development of multiple organ failure and fatal outcome. Further, pNGAL may be increased in patients with COPD without AKI and is related to COPD severity. Therefore, it has been suggested that pNGAL be used with caution in critically ill patients as a consequence of the confounding factors discussed above.²⁸

In addition, pNGAL and urinary NGAL assays have detected different molecular forms of NGAL, and these various molecular forms have different predictive values as biomarkers of AKI.²⁹

Urine NGAL is an early biomarker of AKI and a predictor of outcomes in critically ill children and adults in the ICU. However, before NGAL is routinely and cost effectively used in the ICU, further work is needed to describe the natural history of AKI and NGAL physiology in the ICU. Future studies should focus on accurate, early identification of AKI and the identification of new therapies.³⁰ Studies of NGAL as a biomarker of AKI in the ICU are summarized in Table 103-1.

■ INTERLEUKIN-18

Interleukin (IL-18) is a proinflammatory cytokine that plays a role in both innate and acquired immune response.³¹⁻³³ In studies in non-ICU patients, urinary IL-18 is an early biomarker of AKI that increases in the urine within 6 hours after AKI in adults and children after cardiopulmonary bypass.³⁴⁻³⁶ Subsequent studies in humans have

TABLE 103-2 Urinary IL-18 as a Biomarker of AKI in the ICU

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |
|---------------|------|---|--------------------------|-----|
| Adults on RRT | 101 | A strong correlation was found between serum IL-18 and the hospital mortality of ICU patients with dialysis-dependent AKI. | ND | 40 |
| ARDS adults | 138 | Urinary IL-18 predicted the development of AKI 24 and 48 h later. Urinary IL-18 on the day of initiation of mechanical ventilation was a strong predictor of mortality. | 0.73 | 37 |
| Children | 137 | The peak levels of IL-18 correlated with the severity of AKI. In nonseptic AKI patients, urinary IL-18 increased 2 days prior to serum creatinine. | ND | 38 |
| Infants | 47 | NGAL, IL-18, and cystatin C, but not KIM-1, differentiated patients with good versus poor outcomes in the early postoperative period. | 0.62 | 93 |
| Adults | 451 | Urinary IL-18 did not reliably predict AKI development but did predict poor clinical outcomes. | 0.67 | 39 |
| Adults | 101 | A strong correlation was found between serum IL-18 and the hospital mortality of ICU patients with dialysis-dependent AKI. | ND | 40 |
| Adults | 4512 | IL-18 predicted AKI. | 0.66 | 41 |

ATN, acute tubular necrosis; ICU, intensive care unit; IL-18, interleukin-18; KIM-1, kidney injury molecule-1; ND, not determined; NGAL, neutrophil gelatinase-associated lipocalin; SCr, serum creatinine.

demonstrated that urinary IL-18 is an early predictive biomarker of AKI in the ICU.³⁷ On multivariable analysis, urinary IL-18 values predicted the development of AKI (defined as a 50% increase in SCr) 24 and 48 hours later. On diagnostic performance testing, urinary IL-18 demonstrated an area under the ROC curve of 73% to predict AKI in the next 24 hours. The presence of sepsis in both control and AKI patients did not have a significant effect on urinary IL-18. On multivariate analysis, the urinary IL-18 value on the day of initiation of mechanical ventilation for acute respiratory distress syndrome was a strong predictor of mortality.³⁷ The finding that urinary IL-18 is an early biomarker of AKI in critically ill adults was reproduced in children.³⁸ Urinary IL-18 rises prior to SCr in nonseptic critically ill children, predicts the severity of AKI, and is an independent predictor of mortality.³⁸

The ability of urinary IL-18, measured within 24 hours of ICU admission, to predict AKI, death, and the need for acute dialysis in 451 ICU patients was prospectively investigated.³⁹ Eighty-six patients developed AKI within 48 hours of enrollment and had higher median urinary IL-18 levels than patients without AKI. The area under the ROC curve for urinary IL-18 to predict the subsequent development of AKI within 24 hours was 0.62 and improved modestly to 0.67 in patients whose enrollment eGFR was greater than 75 mL/min. The highest median urinary IL-18 levels were observed in patients with sepsis at enrollment, those receiving acute dialysis, and those who died within 28 days of ascertainment. After adjustment for a priori selected clinical predictors, urinary IL-18 was an independent predictor of a composite outcome of death or acute dialysis within 28 days. The study concluded that urinary IL-18 did not reliably predict AKI development but did predict poor clinical outcomes in a broadly selected critically ill adult population.

A strong correlation was found between serum IL-18 and the hospital mortality of ICU patients with dialysis-dependent AKI.⁴⁰ Serum samples were collected from 101 critically ill patients with AKI at the initiation of RRT in the ICU, and serum cystatin C, NGAL, and IL-18 were measured. The observed overall mortality rate was 56.4%, confirming the high mortality rate of ICU patients requiring RRT. Serum IL-18 and cystatin C concentrations and APACHE III scores determined on the first day of RRT were independent predictors of hospital mortality. The APACHE III score had the best discriminatory power (0.872 ± 0.041 , $P < 0.001$), whereas serum IL-18 had the best Youden index (0.65) and the highest correctness of prediction (83%).

Urinary IL-18 as a biomarker of AKI in various clinical settings was analyzed in a meta-analysis of prospective studies.⁴¹ Subgroup analysis showed that the area under the ROC curve of urinary IL-18 to predict AKI was 0.66 in ICU or coronary care unit patients.

In summary, the proinflammatory cytokine IL-18 is both a mediator and a biomarker of ischemic AKI.^{42,43} Urinary IL-18 increases before SCr in critically ill adults and children in the ICU and is a predictive biomarker of mortality in the ICU. Studies of IL-18 as a biomarker of AKI in the ICU are summarized in Table 103-2.

KIDNEY INJURY MOLECULE-1

KIM-1 is a putative epithelial cell adhesion molecule containing a novel immunoglobulin domain. KIM-1 mRNA and protein are expressed at low levels in normal kidneys but are increased in post-ischemic kidneys.⁴⁴

Urinary KIM-1 and netrin-1 were studied as early biomarkers of septic AKI in the ICU.⁴⁵ One hundred fifty septic patients in the ICU were studied at 0, 1, 3, 6, 24, and 48 hours after ICU admission and compared with non-AKI patients. SCr started to increase at 24 hours after ICU admission. KIM-1 increased significantly by 6 hours, peaked at 24 hours, and remained significantly elevated until 48 hours after ICU admission. Netrin-1 levels increased significantly at 1 hour, peaked at 3 to 6 hours, and remained elevated up to 48 hours after ICU admission in septic AKI patients. Urinary KIM-1 levels at 24 hours and 48 hours were higher in nonsurviving than in surviving AKI patients.⁴⁵

The effect of timing on the predictive values of KIM-1, brush border enzymes, and NGAL measured before the rise of SCr in critically ill, nonseptic patients was determined in adult critically ill patients at four time points prior to the rise in SCr.⁴⁶ Patients with sepsis and/or AKI at ICU entry were excluded.

Both NGAL and KIM-1 concentrations gradually increased until AKI diagnosis. π - and α -glutathione S-transferase (GST) peaked 24 hours before AKI and declined rapidly afterward. The predictive values at 24 hours prior to AKI were modest for π - and α -GST, while the predictive value of NGAL 24 hours before AKI showed an area under the ROC curve of 0.79. KIM-1 was a good discriminator at the time of AKI only (area under the ROC curve = 0.73).⁴⁶

In summary, while KIM-1 is a promising biomarker of AKI in non-ICU patients, KIM-1 remains to be proven as an early biomarker of AKI and prognosis in the ICU. Studies of KIM-1 as a biomarker of AKI in the ICU are summarized in Table 103-3.

TUBULAR ENZYMES

The apical membrane of proximal tubular epithelial cells contains numerous microvilli that form the brush border. The brush border contains enzymes that carry out the specialized functions of the

TABLE 103-3 KIM-1 as a Biomarker of AKI

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |

TABLE 103-4 Tubular Enzymuria as a Biomarker of AKI in the ICU

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REFERENCE |
|---------------|----|--|--------------------------|-----------|
| Adults | 38 | Urinary α -GST levels were increased in sepsis but not in AKI patients. Urinary GST levels at ICU admission were higher in all RIFLE groups than in controls. | ND | 52 |
| ED vs. ICU | 77 | Plasma NGAL diagnosed AKI at all times, GST at 8 to 12 hours post insult. Peak 24-hour urinary NGAL independently predicted 30-day mortality and dialysis. | ND | 51 |
| Adults | 26 | GGT, AP, NAG, and GST but not LDH were higher in the AKI group on admission and were useful in predicting AKI. | 0.845-0.950 | 94 |
| Sepsis adults | 40 | Urinary α -GST and π -GST were elevated early on in all patients with sepsis syndrome but were not predictive of AKI. | ND | 49 |

AP, alkaline phosphatase; DPP, dipeptidyl peptidase IV; γ GT, γ -glutamyl transpeptidase; GGT, gamma-glutamyl transferase; GST, glutathione S-transferase; LAP, leucine aminopeptidase; LDH, lactate dehydrogenase; NAG, N-acetyl-glucosaminidase; NEP, neutral endopeptidase; RBP, retinol-binding protein.

proximal tubule. Intracellular enzymes can be released into the urine during AKI. GST isomers are found in the proximal and distal tubular cells. N-acetyl-glucosaminidase (NAG) is mostly found in the proximal tubules, and alkaline phosphatase (AP) and γ -glutamyl transpeptidase (GGT) are other brush border enzymes.

Nearly 30 years ago, tubular enzymes in the urine were measured as a biomarker of AKI.⁴⁷ Tubular enzymuria may be very sensitive to tubular injury from multiple causes such as tubulointerstitial nephritis and chronic glomerulonephritis.⁴⁸

Urinary α -GST and π -GST were measured at 48 hours after ICU admission in 40 consecutive septic patients.⁴⁹ In this study, urinary π -GST was elevated early on in all patients with sepsis syndrome but was not predictive of AKI as defined by AKIN. GGT, AP, NGAL, cystatin C, KIM-1 and IL-18 were investigated in a prospective observational study of 529 patients in two general ICUs.⁵⁰ On ICU entry, no biomarker had an area under the curve of above 0.7 in the diagnosis or prediction of AKI. NGAL, CysC, and IL-18, but not KIM-1, predicted dialysis (area under the ROC curve over 0.7) and death at 7 days (area under the ROC curve between 0.61 and 0.69). In this study, brush border enzymes did not perform well as biomarkers of AKI.

Biomarker performance on arrival in the emergency department (ED) was compared with subsequent performance in the ICU.⁵¹ Urinary and pNGAL, urinary cystatin C, urinary AP, urinary GGT and GST, and albumin were measured on ED presentation, at 0, 4, 8, and 16 hours and days 2, 4, and 7 in the ICU in patients after cardiac arrest, sustained or profound hypotension, or ruptured abdominal aortic aneurysm. It was concluded that early measurement of biomarkers of AKI in the ED has utility but is not better than measurement later in the ICU. Urinary NGAL best predicted mortality or dialysis compared with other biomarkers.⁵¹

The potential of urinary levels of α -GST and π -GST—markers of proximal and distal renal tubule damage, respectively—for the early diagnosis of AKI in the ICU was investigated in 38 patients.⁵² The urinary α -GST levels were not increased in patients who developed AKI versus those who did not and were elevated early on in all patients with sepsis syndrome.

In summary, the measurement of tubular enzymuria is inexpensive and easy. However, tubular enzymuria may be increased with multiple causes of tubular injury, including acute tubular necrosis, acute rejection, and acute tubulointerstitial nephritis and may be too sensitive for use in the ICU. Studies of tubular enzymes as biomarkers of AKI in the ICU are summarized in Table 103-4.

■ CYSTATIN C

Cystatin C is a 13-kD protein produced by all nucleated cells. It is freely filtered by the glomerulus, completely reabsorbed by the proximal tubules, and is not secreted by the renal tubules.⁵³ Thus, some of the limitations of SCr—for example, the effect of muscle mass, diet, gender, and tubular secretion—may not be a problem with cystatin C. Cystatin C is best measured using an immunonephelometric assay and is a better marker of GFR than SCr.^{48,54,55} Increases in cystatin C occur sooner after changes in kidney function than SCr.⁵⁶ In critically ill patients, serum cystatin C correlated better with GFR than did creatinine and was diagnostically superior to creatinine.⁵⁷ Serum cystatin C and beta-2 microglobulin were found to be better than SCr in the detection of AKI in critically ill children.⁵⁸

Cystatin C rapidly detects AKI in the ICU.⁵⁹ In 442 patients, cystatin C and creatinine were measured on admission to the ICU and then daily for 7 days. Cystatin C predicted sustained AKI with an area under the ROC curve of 0.80. Cystatin C and creatinine were moderately predictive of death or dialysis, with areas under the ROC curves of 0.61 and 0.60, respectively.

The performance of serum cystatin C and SCr as biomarkers of GFR in 47 critically ill patients was compared with GFR.⁶⁰ The areas under the ROC curves to detect a GFR of less than 60 mL/min were 0.799 and 0.942 for SCr and serum cystatin C, respectively. It was concluded that serum cystatin C outperforms SCr for the detection of an impaired GFR in critically ill patients.⁶⁰

The impact of sepsis on the levels of plasma cystatin C in AKI and non-AKI patients was determined.⁶¹ Three hundred twenty-seven ICU patients were divided on the basis of the presence or absence of sepsis

TABLE 103-5 Cystatin C in AKI in the ICU

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |
|---------------------|-----|--|--------------------------|-----|
| Adults septic shock | 6 | Serum cystatin C showed limited value in determining the residual renal function in septic patients. | ND | 95 |
| Noncardiac children | 160 | NGAL was most diagnostic of AKI as defined by cystatin C. Combining serum creatinine and serum cystatin C improved the diagnostic performance. | 0.69 | 63 |
| Adults | 151 | Serum and urine cystatin C were poor biomarkers for AKI and RRT in the ICU. | 0.66 | 62 |
| Adults | 327 | Cystatin C or creatinine did not differ significantly between septic and nonseptic patients. Cystatin C predicted a composite outcome. | 0.78-0.80 | 61 |
| Adults | 47 | Serum cystatin C outperformed serum creatinine for the detection of an impaired GFR in critically ill patients. | 0.94 | 60 |
| Adults | 50 | Serum cystatin C correlated better with GFR (creatinine clearance) than serum creatinine. | 0.927 | 57 |
| Adults | 422 | Cystatin C rapidly detected AKI in the ICU and predicted sustained AKI. | 0.80 | 59 |
| Children | 25 | Serum cystatin C and B2M were better than creatinine in the identification of a creatinine clearance of under 80 mL/min. | 0.792-0.851 | 58 |

AKI, acute kidney injury; B2M, beta-2 microglobulin; GFR, glomerular filtration rate; NGAL, neutrophil gelatinase-associated lipocalin; RRT, renal replacement therapy; SCr, serum creatinine.

and AKI. The change in cystatin C or creatinine did not differ significantly between the septic and nonseptic patients with or without AKI. In another study of 150 ICU patients, serum and urine cystatin C were found to be poor biomarkers for AKI and RRT in the ICU.⁶² The area under the ROC curve to predict AKI for serum cystatin C was fair at 2 days before AKI (0.72) and poor at 1 day before AKI (0.62). Serum and urine cystatin C on Day 0 were poor predictors for the need for RRT (area under the ROC curve ≤ 0.66).⁶² Cystatin C was evaluated as an early biomarker of AKI in 160 noncardiac critically ill children.⁶³ NGAL was most diagnostic of AKI as defined by cystatin C (area under the ROC curve = 0.69); further, IL-18 was most diagnostic for AKI as defined by SCr (area under the ROC curve = 0.69).

There are limitations to the use of cystatin C as a marker of GFR. Abnormalities of thyroid function⁶⁴ and glucocorticoid therapy^{65,66} may affect cystatin C independent of kidney function. The levels of C-reactive protein may increase cystatin C levels, and it has been suggested that cystatin C is a marker of inflammation.⁶⁷

In summary, serum cystatin C is at least equal if not superior to SCr as a marker of GFR and is independent of height, gender, age, and muscle mass. Three studies show that serum cystatin C is an early marker of AKI in the ICU, and it does not seem to be influenced by sepsis. Studies of cystatin C as a biomarker of AKI in the ICU are summarized in Table 103-5.

■ CYTOKINES

Both IL-6 and IL-8 are proinflammatory cytokines and have been studied as predictors of AKI. In one clinical trial, 547 patients from the placebo group of the Prospective Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) dataset were studied.⁶⁸ Of these 547 patients, 127 (23.2%) developed AKI. Using multivariate Cox regression, the predictors of AKI were log IL-6 and the APACHE II score.

The Program to Improve Care in Acute Renal Disease (PICARD) was a prospective multicenter cohort study designed to examine the natural history and outcomes of critically ill ICU patients with established AKI.⁶⁹ Serum IL-1 β , tumor necrosis factor (TNF)- α , IL-6, IL-8, C-reactive protein, and IL-10 were determined in a subset of 98 patients from the PICARD study at the time of enrollment and then weekly for the duration of their hospital stay. Patients were enrolled into PICARD at the time of their nephrology consultation and thus had established AKI. The proinflammatory cytokines IL-1 β , TNF- α , IL-6, and IL-8 and the antiinflammatory cytokine IL-10 were significantly elevated compared with those in healthy controls. Increased

serum levels of IL-6, IL-8, and IL-10 at baseline were significantly correlated with increased in-hospital mortality in AKI patients. Thus, the cytokine response in patients with AKI is significantly dysregulated. When cytokine values were further adjusted for the severity of illness (APACHE III scores), only IL-6 remained an independent predictor of mortality. Thus, IL-6 may be an important biomarker of outcomes in patients with AKI.

A study examined the relationship between increases in plasma IL-6, IL-8, and IL-10 on outcomes in critically ill ICU patients with AKI.⁷⁰ In this study, plasma IL-6, IL-8, and IL-10 were determined in 103 consecutive critically ill ICU patients with SIRS, with or without AKI.⁷⁰ Plasma cytokines were determined prospectively on the day of admission and 2 days after. Patients with AKI had significantly higher levels of plasma IL-6, IL-8, and IL-10 than patients without AKI.

IL-6 and other proinflammatory markers were studied in 879 patients in the low-tidal-volume versus high-tidal-volume mechanical ventilation study database of the first Acute Respiratory Distress Syndrome Clinical Network (ARDS-net) trial.⁷¹⁻⁷³ AKI was defined by an increase in SCr of at least 50% from baseline. Baseline values of IL-6, IL-8, IL-10, von Willebrand factor, TNF- α , type I and II soluble TNF receptors (sTNF-I and -II), protein C, plasminogen activator inhibitor-1 (PAI-1), surfactant protein-A, surfactant protein-D, and intercellular adhesion molecule-1 were correlated with the development of AKI. After adjustments for demographics, interventions, and the severity of illness, increased levels of IL-6, sTNF-I, sTNF-II, and PAI-1 levels were independently associated with the development of AKI.

In summary, in both patient and animal studies, early AKI is associated with a proinflammatory burst that is characterized by early increases in serum IL-6 and KC/IL-8. Such a proinflammatory burst may also be linked with other complications in the ICU such as acute lung injury.^{74,75} Studies of cytokines as biomarkers of AKI in the ICU are summarized in Table 103-6.

■ LIVER FATTY ACID-BINDING PROTEIN

Fatty acid-binding proteins (FABPs) are a family of carrier proteins for fatty acids and other lipophilic substances including eicosanoids and retinoids. FABPs also transport lipophilic molecules from the outer cell membrane to intracellular receptors such as peroxisome proliferator-activated receptors.

Urinary and serum liver-FABP (L-FABP) were measured in 80 critically ill patients.⁷⁶ Urinary L-FABP levels in patients with septic shock were significantly higher than those in patients with severe sepsis without shock, patients with AKI, or healthy subjects ($P < 0.001$).

TABLE 103-6 Cytokines as Biomarkers of AKI in the ICU

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |
|------------------------|-----|---|--------------------------|----------|
| Adults | 879 | Increased levels of IL-6, sTNFR1, sTNFR2, and PAI-1 were independently associated with the development of AKI. | | 71,72,73 |
| Adults | 103 | Patients with AKI had significantly higher levels of plasma IL-6, IL-8, and IL-10 than patients without AKI. | ND | 70 |
| Adults | 98 | IL-1 β , TNF α , IL-6, IL-8, and IL-10 were significantly elevated. Increased serum IL-6, IL-8, and IL-10 at baseline was correlated with increased in-hospital mortality in AKI patients. | ND | 69 |
| Severe sepsis patients | 547 | Increased log plasma IL-6 and APACHE II score were significant risk factors of AKI. | | 68 |
| Septic shock | 537 | Elevated serum TNF-R1 and RII were associated with the development of ARF. TNF-R was an independent predictor of mortality in AKI patients. | | 96 |

ATF3, activating transcription factor 3; ATN, acute tubular necrosis; β 2M, beta-2 microglobulin; CPB, cardiopulmonary bypass; GGT, gamma-glutamyl transferase; IL-6, interleukin-6; IL-8, interleukin-8; IL-10, interleukin-10; IL-1 β , interleukin-1 beta; NAG, N-acetyl-glucosaminidase; PAI-1, plasminogen activator inhibitor-1; PKD, polycystic kidney disease; sTNFR1, soluble tumor necrosis factor receptor1; sTNFR2, soluble tumor necrosis factor receptor2; TNF- α , tumor necrosis factor alpha.

TABLE 103-7 L-FABP as a Biomarker of AKI in the ICU

| SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |
|-----------|-----|---|--------------------------|-----|
| Adults | 80 | Urinary L-FABP levels in patients with septic shock were significantly higher than those in patients with severe sepsis without shock, patients with ARF, and healthy subjects. | ND | 76 |
| Adults | 145 | AKI patients had significantly higher levels of urinary NGAL and L-FABP, as well as higher mortality. Urinary L-FABP was an independent predictor for 90-day mortality. | 0.73-0.78 | 77 |
| Adults | 337 | Mortality in AKI patients diagnosed by serum creatinine was increased remarkably when urinary L-FABP and NAG were positive. | 0.75 | 97 |

L-FABP, L-type fatty acid binding protein; NAG, N-acetyl glucosaminidase; NGAL, neutrophil gelatinase-associated lipocalin.

Serum L-FABP levels showed no significant differences between patients with septic shock, patients with severe sepsis, patients with AKI, and healthy subjects.

The diagnostic and prognostic abilities of urinary L-FABP in heterogeneous critically ill patients were determined.⁷⁷ Urine NGAL and L-FABP were measured in 145 medical and surgical patients at the time of ICU admission. AKI patients had significantly higher levels of urinary NGAL and L-FABP, as well as higher mortality rates than non-AKI patients. The area under the ROC curve was 0.773 for NGAL and 0.780 for L-FABP for the diagnosis of AKI. On multivariate Cox analysis, urinary L-FABP was an independent predictor for 90-day mortality. Thus, urinary L-FABP is promising both for the diagnosis of AKI and for the prediction of prognosis in heterogeneous ICU patients.⁷⁷ Studies of L-FABP as a biomarker of AKI in the ICU are summarized in Table 103-7.

■ OTHER BIOMARKERS OF AKI

Information on additional biomarkers of AKI is given in Table 103-8. In one study, 340 candidate biomarkers were measured in critically ill ICU patients with sepsis or one or more risk factors for AKI such as hypotension, sepsis, and major trauma. In the initial analysis, the biomarkers were ranked by their ability to predict RIFLE I and F within 12 to 36 h. The two best biomarkers were the cell cycle arrest proteins, urinary insulin-like growth factor-binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinases-2 (TIMP-2), which are both inducers of G1 cell cycle arrest, a key mechanism implicated in AKI.⁷⁸ In the Sapphire validation study, in 728 critically ill patients, the primary endpoint was moderate to severe AKI ([Kidney Disease: Improving Global Outcomes] KDIGO stage 2 to 3) within 12 hours of sample collection.⁷⁸ IGFBP7 and TIMP-2 demonstrated an area under the curve of 0.80 (0.76 and 0.79 alone) for the primary endpoint. Urine concentrations of IGFBP7 and TIMP-2 were significantly superior to all previously described markers of AKI ($P < 0.002$), none of which

achieved an area under the curve of more than 0.72. In the Topaz study, in 420 ICU patients, a predefined cut-off value of IGFBP7 and TIMP-2 was prospectively validated for risk assessment in AKI diagnosed by a clinical adjudication committee.⁷⁹ Critically ill patients with urinary [TIMP-2].[IGFBP7] greater than 0.3 had seven times the risk of AKI compared with critically ill patients with a test result below 0.3. Urinary TIMP-2 and IGFBP7 greater than 0.3 identified patients at risk for imminent AKI. In addition, urinary TIMP-2 and IGFBP7 are associated with adverse long-term outcomes in patients with AKI.⁸⁰ The measurement of TIMP-2 and IGFBP7 has been marketed as “Nephro Check” and has been the first set of biomarkers to be approved by the FDA for the detection of AKI in ICU patients.

CD163 is a scavenger receptor for haptoglobin-hemoglobin complexes that is almost exclusively expressed by monocytes and macrophages and is shed (as soluble [sCD163]) by inflammatory stimuli. In one study, 1657 critically ill patients randomized to “conventional” or “intensive” insulin therapy were compared with healthy controls.⁸¹ On admission, critically ill patients had 1.6-fold higher sCD163 levels than controls ($P < 0.0001$). Long-stay patients (ICU stay >5 days), non-survivors, and patients who developed liver dysfunction or kidney injury had higher baseline sCD163 levels. On multivariable analysis, elevated baseline sCD163 levels were independently associated with ICU mortality, liver dysfunction, and time to discharge from the ICU and hospital. sCD163 further increased during the ICU stay in patients who developed organ dysfunction and in nonsurvivors. This study demonstrated the association of elevated sCD163 with organ dysfunction and adverse outcomes in critically ill patients.⁸¹

The diagnostic value of urine sCD163 for the identification of sepsis, the severity of sepsis, AKI, and prognosis was determined in 60 ICU patients and 20 controls.⁸² There were higher levels of urine sCD163 on the day of ICU admission in the sepsis group compared with the SIRS group. The area under the curve was 0.83, with a sensitivity of 0.83 and a specificity of 0.75 for the sepsis group. The urine sCD163 levels at AKI diagnosis were significantly higher than those

TABLE 103-8 Other Biomarkers of AKI in the ICU

| BIOMARKER | SITUATION | N | STUDY | AREA UNDER THE ROC CURVE | REF |
|------------------------------------|---------------|-----|--|--------------------------|-----|
| Urinary TIMP-2 and IGFBP7 combined | Adults | 728 | Urinary TIMP-2 and IGFBP7 predicted the primary endpoint: moderate to severe AKI (KDIGO stage 2 to 3) within 12 hours of sample collection. | 0.80 | 78 |
| Urinary TIMP-2 and IGFBP7 combined | Adults | 692 | [TIMP-2][IGFBP7] measured early on in the setting of critical illness may identify patients with AKI at increased risk for mortality or receipt of RRT over the next 9 months. | | 80 |
| sCD163 | Adults | 80 | There is a potential value of urine sCD163 levels for identifying sepsis and AKI. | 0.83 | 82 |
| sTREM-1 | Adults | 104 | The sepsis group had higher levels of urine sTREM-1 and APACHE II scores. Urine sTREM-1, SCr, and BUN levels increased at 48 h before AKI. | ND | 84 |
| RBP4 | Adults | 123 | RBP4 was significantly decreased in critically ill patients and was associated with hepatic and renal function, insulin resistance, and acute mortality. | ND | 85 |
| Ang-2 | Adults on RRT | 117 | Ang-2 levels were higher in AKI patients with RIFLE category—injury or failure. Ang-2 was a strong and independent predictor of mortality in dialysis-dependent ICU patients. | ND | 86 |
| Resistin | Adults | 230 | Serum resistin was elevated in sepsis and was associated with renal failure and unfavorable outcomes. | ND | 87 |

Ang-2, angiotensin-2; AOPPs, advanced oxidation protein products; BNP, brain natriuretic hormone; IGFBP7, urine insulin-like growth factor-binding protein 7; ND, not determined; RBP4, retinol-binding protein 4; sCD163, soluble, hemoglobin-scavenging receptor; sTREM-1, soluble triggering receptor expressed on myeloid cells-1; TIMP2, tissue inhibitor of metalloproteinases-2; TREM-1, triggering receptor expressed on myeloid cells 1.

present in the sepsis patients at ICU admission. The study shows the potential value of urine sCD163 levels for identifying sepsis and AKI.⁸²

Triggering receptor expressed on myeloid cells 1 (TREM-1) is an amplifier of the innate immune response. Its soluble form (sTREM-1) acts as a decoy for the natural TREM-1 ligand and dampens its activation. sTREM-1 has received attention as a biomarker of sepsis in the ICU.⁸³ Urine sTREM-1 was evaluated for early sepsis identification, severity and prognosis assessment, and diagnosis of AKI in 104 patients in the ICU.⁸⁴ On the day of admission to the ICU, compared with the SIRS group, the sepsis group exhibited higher urine sTREM-1 levels and APACHE II scores. Urine sTREM-1 was higher in patients with severe sepsis as compared with those with sepsis. Urine sTREM-1 was increased among the nonsurvivors. For the 17 patients with AKI, urine sTREM-1, SCr, and BUN levels at 48 h before AKI diagnosis were higher than those in non-AKI subjects. Urine sTREM-1 was more sensitive than white blood cells, serum C-reactive protein, and serum procalcitonin for the early diagnosis of sepsis and for prognosis. Thus, urine sTREM-1 may also be an early marker of AKI in sepsis patients.⁸⁴

Retinol-binding protein 4 (RBP4) promotes insulin resistance in mice and is systemically elevated in patients with obesity and type 2 diabetes. RBP4 was measured in 123 critically ill patients on admission to a medical ICU and compared with that in 42 healthy nondiabetic controls.⁸⁵ Low serum RBP4 upon admission was an adverse predictor of short-term survival in the ICU but was not associated with overall survival during long-term follow-up.

Endothelial activation has emerged as an early event in the pathogenesis of microcirculatory dysfunction, capillary leakage and multi-organ dysfunction syndrome. Angiotensin-2 (Ang-2), a circulating antagonistic ligand of the endothelial-specific Tie2 receptor, has been identified as a nonredundant gatekeeper of endothelial activation. Ang-2 was examined as an outcome-specific biomarker in 117 critically ill patients requiring RRT in the ICU.⁸⁶ Circulating Ang-2 levels were significantly higher in AKI patients with RIFLE I or F compared with patients with RIFLE R. Elevated levels of circulating Ang-2 correlated with impaired oxygenation, low mean arterial pressure, vasopressor dose and the sequential organ failure assessment (SOFA) score. Ang-2 concentrations were significantly higher in nonsurvivors than in survivors at day 0 and 14 after the initiation of RRT. The study concluded that circulating Ang-2 is a strong and independent predictor of mortality in dialysis-dependent ICU patients.⁸⁶

Resistin is a hormone that is mainly derived from macrophages in humans and from adipose tissue in rodents. Resistin regulates glucose

metabolism and insulin sensitivity. Resistin was prospectively measured on admission to the medical ICU in 170 patients and compared with that in 60 healthy nondiabetic controls.⁸⁷ Serum resistin was significantly elevated in all critical care patients compared with the healthy controls and was also found to be significantly higher in sepsis than in nonsepsis patients. Serum resistin concentrations were closely correlated to inflammatory parameters such as C-reactive protein and cytokines such as IL-6 and TNF- α and were also associated with renal failure and liver synthesis capacity. High resistin levels (>10 ng/mL) were associated with an unfavorable outcome in nonsepsis patients in the ICU and poor overall survival.⁸⁷

In summary, novel biomarkers of AKI in the ICU have recently been identified. These biomarkers include the cell cycle arrest biomarkers (IGFBP7 and TIMP-2), sCD163, urinary sTREM-1, RBP4, advanced oxidation protein products, Ang-2, and resistin.

COMBINATIONS OF AKI BIOMARKERS

The classical biomarker paradigm is that one test detects one disease—for example, troponin for acute myocardial infarction and prostate-specific antigen for prostate cancer. However, AKI is a complex disease with multiple causes, and it is possible that a panel of biomarkers may be necessary.⁸⁸

The diagnostic performance of nine urinary biomarkers of AKI was evaluated in 204 patients with or without AKI, healthy volunteers, patients undergoing cardiac catheterization, and patients admitted to the ICU.⁸⁹ The biomarkers studied were KIM-1, NGAL, IL-18, hepatocyte growth factor (HGF), cystatin C, NAG, vascular endothelial growth factor (VEGF), chemokine interferon-inducible protein 10 (IP-10; CXCL10), and total protein. Using a logistic regression model, the area under the curve (0.94) was greater for the combination of biomarkers than for the individual biomarkers. Age-adjusted levels of urinary KIM-1, NAG, HGF, VEGF, and total protein were significantly higher in patients who died or required RRT compared with those who survived or did not need RRT.

In summary, more than one biomarker may be necessary to obtain sufficient sensitivity and specificity for AKI screening.

CONCLUSION

The clinical application of biomarkers is difficult in critically ill patients because the timing of the renal insult is often unknown,

sepsis may lead to false positives, and the pathophysiology of AKI in sepsis patients is complex and not due only to ischemia and hypotension.⁹⁰ Plasma biomarkers may be an indication of the severity of disease rather than of true AKI.⁹⁰ Finding the ideal biomarker of AKI and prognosis in the ICU is a subject of intense investigation. Problems and prospects related to biomarker investigation in ICU patients have been reviewed in depth.⁹⁰ However, despite the issues mentioned above, there are multiple promising serum and urinary

biomarkers of AKI in the ICU, including urinary levels of IGFBP7, TIMP-2, IL-18, NGAL, KIM-1, cystatin C, and L-FABP, which detect AKI before the rise in SCr and predict the outcome in patients with AKI. Ultimately, disease control studies are necessary to determine the impact of biomarker screening on reducing the burden of disease.

■ ACID-BASE DISORDERS

Acid-base disorders are common in the intensive care unit (ICU) and can contribute to significant morbidity and mortality. Appropriate management of acid-base disorders in the ICU requires timely recognition of the disorder, accurate interpretation of the disturbance, identification of the cause, and knowledge of the treatment.

Acid-base disorders can be quantified by the physiologic, base-excess, and physiochemical approaches (Stewart method).¹ This chapter focuses on the physiologic approach with the bicarbonate-carbonic acid buffer system.

Normal Acid-Base Homeostasis

On a daily basis, the body's metabolic processes generate 10,000 to 15,000 mEq of volatile acids and 1 to 2 mEq/kg of fixed acids that must be buffered and excreted to maintain the pH within a narrow range of 7.35 to 7.45. Chemical buffers and the pulmonary and renal systems operate interdependently to regulate and maintain acid-base balance. The most important buffer is the bicarbonate-carbonic acid (HCO_3^- - H_2CO_3) system, which acts immediately to buffer the extracellular fluid. The relationship between pH, HCO_3^- , and carbon dioxide (CO_2) is described by the Henderson-Hasselbalch equation:

$$\text{pH} = 6.10 + \log \left(\frac{[\text{HCO}_3^-]}{[0.03 \times \text{PCO}_2]} \right)$$

The number 6.10 represents the dissociation constant for the reaction; 0.03 represents the solubility coefficient of CO_2 in blood. PCO_2 is the partial pressure of CO_2 in the blood.²

Normal acid-base status is maintained by pulmonary excretion of volatile acids and by renal excretion of fixed acids and formation of bicarbonate. In order to maintain acid-base balance, the kidney must reabsorb all of the filtered bicarbonate (about 4000 mEq/day) and excrete the fixed daily acid load. Reabsorption occurs mostly in the proximal tubule (>90%) and, to a lesser degree, in the collecting tubule. Renal excretion of acid is achieved by combining hydrogen ions (H^+) with urinary buffers to be excreted as titratable acids, such as phosphate, urate, and creatinine, or with ammonia to form ammonium.³ The ammonia buffering system is especially important because other buffers are filtered in fixed concentrations and can be depleted by high acid loads; by contrast, tubular cells actively regulate ammonia production in response to changes in acid load.

When acid-base derangements occur, the blood pH is returned toward normal initially by chemical buffering, followed by pulmonary ventilation, and finally by renal regulation of acid-base excretion. The Paco_2 is finely regulated by changes in tidal volume and minute ventilation. A decrease in pH is sensed by arterial chemoreceptors and leads to increases in tidal volume or respiratory rate. Pulmonary regulation occurs over minutes to hours. The kidney controls pH through the regulation of H^+ excretion, bicarbonate reabsorption, and the production of new bicarbonate. Reabsorption of bicarbonate is equivalent to removing free H^+ . Changes in renal acid-base handling occur hours to days after changes in acid-base status.

Acid-Base Pathophysiology

Terminology and Classification

Acid-base disorders occur when a change in the normal value of the blood pH results from abnormal renal or pulmonary function or when an acid or base load overwhelms excretory capacity. *Acidemia* refers to

a decrease in the blood pH below the normal range, while *alkalemia* refers to an increase in the blood pH above the normal range. *Acidosis* is a process that tends to decrease the blood pH and occurs by a fall in the plasma bicarbonate concentration and/or an elevation in Paco_2 . In contrast, *alkalosis* is a process that tends to raise the blood pH through an elevation in the plasma bicarbonate concentration and/or a fall in Paco_2 . Although acidemia cannot be present without acidosis and alkalemia cannot be present without alkalosis, acidosis or alkalosis can exist at any blood pH.

The four primary acid-base disorders are classified as respiratory or metabolic. A respiratory disturbance occurs when acidosis or alkalosis results from a primary change in the Paco_2 . Respiratory acidosis is a disorder that elevates the Paco_2 and reduces the pH; respiratory alkalosis is a disorder that reduces the Paco_2 and elevates the pH. A metabolic disturbance occurs when acidosis or alkalosis results from a primary change in the plasma bicarbonate concentration. Metabolic acidosis is a disorder that reduces the plasma bicarbonate concentration and pH; metabolic alkalosis is a disorder that elevates the plasma bicarbonate concentration and pH. Compensation refers to physiologic respiratory and renal changes by which the body attempts to return the pH toward normal in response to primary acidosis or alkalosis.^{4,5} Compensation does not return the pH back to a completely normal value.

A simple acid-base disorder is a single primary acid-base disorder (respiratory acidosis, respiratory alkalosis, metabolic acidosis, or metabolic alkalosis) with appropriate respiratory or renal compensation for that disorder. A mixed acid-base disorder is characterized as the simultaneous presence of two or more primary acid-base disorders and is frequently encountered in ICU patients. The arterial blood pH will depend on the direction and magnitude of disturbances. Mixed acid-base disorders can be suspected from the patient's history and whenever the measured compensatory values of either bicarbonate or Paco_2 differ significantly from what is expected.

Compensatory Responses

Disturbances in acid-base balance lead to predictable responses that serve to limit the magnitude of change of the blood pH. The expected compensatory responses to primary acid-base disturbances are listed in Table 104-1.^{5,6} The magnitude of the compensatory response is proportional to the severity of the primary acid-base disturbance. The Henderson-Hasselbalch equation shows that pH is determined by the ratio of the plasma HCO_3^- concentration and Pco_2 , not by either value in isolation.⁶ In each acid-base disorder, compensatory renal or respiratory responses act to minimize the change in pH by minimizing alterations in the ratio. Metabolic disorders result in respiratory compensation (change in Paco_2); respiratory acid-base disorders result in metabolic compensation (change in HCO_3^- concentration).

In metabolic acidosis, a low plasma HCO_3^- concentration decreases the pH, stimulating medullary chemoreceptors to increase ventilation and thereby decrease Paco_2 and restore the pH toward normal. In general, for metabolic acidosis, respiratory compensation results in a 1.25-mm Hg decrease in Paco_2 for every 1.0-mEq/L reduction in the plasma HCO_3^- concentration down to a minimum Paco_2 of 10 to 15 mm Hg.⁶ The expected Paco_2 in a simple metabolic acidosis can be calculated by Winters' formula⁷:

$$\text{Paco}_2 = 1.5 \times (\text{HCO}_3^-) + 8 \pm 2$$

This formula may be used in patients with metabolic acidosis to evaluate whether the observed Paco_2 is an appropriate compensatory

TABLE 104-1 Acid-Base Abnormalities and Appropriate Compensatory Responses for Simple Disorders

| PRIMARY ACID-BASE DISORDERS | PRIMARY DEFECT | EFFECT ON pH | COMPENSATORY RESPONSE | EXPECTED RANGE OF COMPENSATION | LIMITS OF COMPENSATION |
|-----------------------------|---|--------------|--|--|--|
| Respiratory acidosis | Alveolar hypoventilation (\uparrow P_{CO_2}) | \downarrow | \uparrow Renal HCO_3^- reabsorption ($HCO_3^- \uparrow$) | Acute: $\Delta[HCO_3^-] = +1$ mEq/L for each $\uparrow \Delta P_{CO_2}$ of 10 mm Hg Chronic: $\Delta[HCO_3^-] = +4$ mEq/L for each $\uparrow \Delta P_{CO_2}$ of 10 mm Hg | $[HCO_3^-] = 38$ mEq/L $[HCO_3^-] = 45$ mEq/L |
| Respiratory alkalosis | Alveolar hyperventilation (\downarrow P_{CO_2}) | \uparrow | \downarrow Renal HCO_3^- reabsorption ($HCO_3^- \downarrow$) | Acute: $\Delta[HCO_3^-] = -2$ mEq/L for each $\downarrow \Delta P_{CO_2}$ of 10 mm Hg Chronic: $\Delta[HCO_3^-] = -5$ mEq/L for each $\downarrow \Delta P_{CO_2}$ of 10 mm Hg | $[HCO_3^-] = 18$ mEq/L $[HCO_3^-] = 15$ mEq/L |

response or whether there is additional respiratory acidosis (P_{aCO_2} greater than predicted) or respiratory alkalosis (P_{aCO_2} less than predicted).⁵

Respiratory compensation to metabolic alkalosis should raise the P_{CO_2} by about 0.6 to 0.75 mm Hg for every 1-mEq/L increase in the plasma bicarbonate concentration.^{6,7,8} The expected P_{aCO_2} may be estimated by the following formula:

$$P_{aCO_2} = 40 + ([\text{current } HCO_3^-] - 24) \times 0.7$$

In metabolic alkalosis, a high pH induces hypoventilation with a resultant rise in P_{aCO_2} and decrease in pH. However, hypoxemia induced by progressive hypoventilation eventually activates oxygen-sensitive chemoreceptors to stimulate ventilation and generally limits the compensatory pulmonary response to a P_{aCO_2} of <55 mm Hg.⁷

METABOLIC ACIDOSIS

Metabolic acidosis occurs through increased bicarbonate loss, decreased excretion of acid, an imbalance between production and consumption of endogenous acids, or ingestion or intravenous administration of exogenous acidosis. The clinical significance of metabolic acidosis depends on the severity of the disorder. Without appropriate intervention, metabolic acidosis can progress to life-threatening changes in cardiac, neurologic, and metabolic function as listed in Box 104-1.⁹ Metabolic acidosis can be classified as high-anion gap (AG) metabolic acidosis or non-AG (hyperchloremic) metabolic acidosis.

Serum Anion Gap

Calculation of the serum AG is a useful tool in the evaluation of metabolic acidosis. The serum AG represents the difference in the measured cations (mainly sodium) and the measured anions (chloride and bicarbonate). Mathematically, this is represented as follows:

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

Based on the law of electroneutrality, the concentration of cations should be equal to the concentration of anions in the human body. The serum AG appears on laboratory testing because certain cations and anions are not measured on routine laboratory chemistry panels. This can be represented as follows:

$$\begin{aligned} Na^+ + \text{Unmeasured Cations (UC)} \\ = Cl^- + HCO_3^- + \text{Unmeasured Anions (UA)} \end{aligned}$$

BOX 104-1 Systemic Effects of Acidosis

NEUROLOGIC

- Obtundation and coma
- Hyperactivity of sympathetic nervous system
- Decreased cerebral metabolism
- Decreased response to catecholamines

RESPIRATORY

- Increased minute ventilation
- Subjective dyspnea
- Respiratory muscle fatigue

CARDIOVASCULAR

- Decreased contractility of myocardium
- Core vasculature blood pooling (venoconstriction and arterial dilatation)
- Decreased cardiac response to catecholamines
- Tachyarrhythmias

METABOLIC

- Hyperkalemia (inorganic acidemia)
- Hyperphosphatemia
- Increased protein catabolism

Therefore:

$$AG = Na^+ - (Cl^- + HCO_3^-) = UA - UC$$

Calcium, magnesium, gamma globulins, and potassium are the major “unmeasured” cations and account for approximately 11 mEq/L under normal conditions (Fig. 104-1). Although potassium is routinely measured in chemistry panels, the concentration of potassium in the blood is relatively small compared with that of sodium, chloride, and bicarbonate, so potassium is not typically included as a “measured” cation in the AG equation. Negatively charged plasma proteins (albumin), sulfates, phosphates, and other organic anions are the major “unmeasured” anions and account for 20 to 24 mEq/L. Thus, the normal AG is about 12 mEq/L (23–11). Under normal circumstances, the serum AG is typically 12 ± 4 mEq/L but can vary depending on the laboratory method used.¹⁰ Therefore, the established normal range provided by the particular laboratory that performs the testing should be used.

FIGURE 104-1 ■ Components of the serum anion gap.

The AG can be affected by increases or decreases in the UC or UA. The most important contributor to a normal serum AG is albumin, which has a negative charge at a physiologic pH. In patients with hypoalbuminemia, as commonly observed in critical illness, the AG must be corrected for low albumin. For each 1-g/dL fall in the plasma albumin concentration from a normal albumin concentration, the AG falls about 2.5 mEq/L.¹⁰ This can be represented as follows:

$$\text{AG adjusted} = \text{AG} + 2.5 \times (\text{normal albumin} - \text{measured plasma albumin [g/dL]})$$

Other causes of a low AG that may be important to consider for diagnostic and treatment purposes in ICU patients are listed in Table 104-2 and include hypercalcemia, hypermagnesemia, lithium intoxication, hypergammaglobulinemia as occurs in myeloma, and halide (bromide or iodide) intoxication.¹¹

The contributors to serum AG in the normal physiologic state and in high AG and non-AG metabolic acidosis are depicted in Figure 104-2.

■ HIGH-ANION GAP METABOLIC ACIDOSIS

High-AG metabolic acidosis develops from excessive production, ingestion, or retention of a strong acid or a compound metabolized to a strong acid. These include negatively charged acids such as ketones, lactate, sulfates, or metabolites of methanol, ethylene glycol, or salicylate, which accumulate in place of the consumed HCO₃⁻ and cause a high AG. Other causes of an increased AG include hyperalbuminemia or uremia (increased anions) and hypocalcemia or hypomagnesemia (decreased cations)¹¹ (see Table 104-2).

The presence of a significantly elevated AG (AG > 20 mEq/L) always represents metabolic acidosis, regardless of the pH or plasma bicarbonate concentration. Therefore, the serum AG should always be calculated in the ICU setting. In the event of a mixed acid-base disorder with a normal blood pH, a high AG points toward underlying metabolic acidosis, which otherwise may be missed. The common causes of high-AG acidosis in the ICU are lactic acidosis, ketoacidosis, toxin-induced, and renal failure (Box 104-2).

Lactic Acidosis

L-Lactic Acidosis

L-lactic acidosis is among the most frequent causes of elevated AG metabolic acidosis in the ICU and is associated with a high mortality.^{12,13} Lactic acid concentration should be measured directly if lactic acidosis is expected because the serum AG has a sensitivity and

*Albumin is the major unmeasured anion. A decline in serum albumin of 1.0 g/dL from the normal value of 4.5 g/dL decreases the anion gap by 2.3-2.5 mEq/L. Correction is very important to diagnose anion gap acidosis in the setting of hypoalbuminemia.

specificity of <80% in identifying elevated lactate levels.¹⁴ Thus, a normal AG does not rule out lactic acidosis. Jensen et al. have shown that lactate levels serve as a prognosis indicator that can signal underlying deterioration, prompt more aggressive management, and also help avoid unnecessary treatment when the condition stabilizes.¹⁵ Lactic

acidosis occurs whenever production of lactate exceeds its utilization. In most cases of clinically significant lactic acidosis, there is evidence of defective utilization as well as increased production, depending on the etiology of lactic acidosis.

Pyruvate is the precursor of lactate and is produced in the cytoplasm from glucose metabolism via glycolysis by the Embden-Meyerhof pathway. Pyruvate normally undergoes oxidative decarboxylation by mitochondrial pyruvate dehydrogenase (PDH) to acetyl-coenzyme A and then ultimately to CO_2 and H_2O . This process results in the synthesis of 36 moles of adenosine triphosphate (ATP) and requires oxidized nicotinamide adenine dinucleotide (NAD^+). Pyruvate can also enter the Cori cycle in the liver and renal cortex and be converted back to glucose. Oxidative phosphorylation, ATP synthesis and reoxidation of NADH are inhibited during hypoxia. This leads to an increased (NADH/NAD^+) ratio, conversion of pyruvate to lactate, and synthesis of two molecules of ATP, rather than the 36 generated via the tricarboxylic acid cycle. The overall result of anaerobic metabolism is increased lactate levels, an elevated lactate/pyruvate ratio, greater glucose utilization, and lower energy production.

Traditionally, lactic acidosis has been categorized as type A or type B acidosis. Type A lactic acidosis is characterized by an impaired mitochondrial oxidative capacity in the setting of tissue hypoxia, while type B lactic acidosis is due to dysregulation of cell metabolism rather than hypoxia (Box 104-3). Most cases of type A lactic acidosis are due to reduced oxygen delivery as a result of reduced tissue perfusion from shock or cardiopulmonary arrest. Other causes are carbon monoxide poisoning and severe anemia. Type B lactic acidosis is classified as type B1 (related to underlying diseases like malignancies or liver disease),

type B2 (related to the effect of drugs and toxins), and type B3 (associated with inborn errors of metabolism).¹⁶ The most common drugs associated with type B2 lactic acidosis include biguanides, reverse-transcriptase inhibitors, ASA, propofol, and linezolid, among others (see Box 104-3). In critically ill patients, the clinical distinction between type A and B lactic acidosis may not hold; patients can have dysregulation of cellular metabolism as well as hypoxia.¹⁷

Sepsis is a common cause of lactic acidosis in the ICU. The source of lactic acid in sepsis is controversial. Sepsis-induced lactic acidosis has been conventionally classified as type A lactic acidosis due to inadequate oxygen supply and augmented anaerobic metabolism. However, the lack of response to increased oxygen delivery, the absence of tissue hypoxia, and normal tissue ATP levels suggest that lactate formation during sepsis is due to dysregulation of cellular metabolism.^{18,19} Decreased clearance of lactate rather than increased production has been demonstrated in sepsis.²⁰ In addition, increased pyruvate production, decreased PDH activity, regional differences in lactate production, and decreased clearance of lactate have been implicated as possible contributors to lactic acidosis.^{21–23} Decreased muscle PDH activity has been shown in sepsis, and its restoration by dichloroacetate, an activator of PDH, suggesting that lactic acidosis during sepsis is due

to functional inhibition of PDH, with enhanced conversion of pyruvate to lactate.^{24,25}

Treatment of lactic acidosis requires identification and correction of the underlying cause. The therapeutic goal in type A lactic acidosis is restoration of tissue oxygen delivery through hemodynamic and/or respiratory support. The use of sodium bicarbonate in lactic acidosis is controversial and not supported by clinical studies.⁹ Intravenous administration of sodium bicarbonate may increase lactate production, decrease portal vein flow, decrease ionized calcium levels, lower intracellular pH, and worsen cardiac output.^{9,26,27} Bicarbonate increases extracellular pH only if ventilation removes the excess CO₂ generated; otherwise, hypercapnia can lower intracellular pH and impair cellular function.^{9,26,27} Bicarbonate can worsen tissue oxygen delivery if the arterial pH increases more than the intracellular pH, with a leftward shift in the oxyhemoglobin dissociation curve. If tissue hypoxia is present, the use of bicarbonate can stimulate glycolysis mediated by the pH-sensitive rate-limiting enzyme phosphofructokinase and paradoxically increase lactate production.²⁸ Sodium bicarbonate should be administered cautiously when the arterial pH is less than 7.15 since a pH below this value will promote the development of decreased responsiveness to catecholamines, arrhythmias, cardiac depression, and hemodynamic instability.⁹

Alternative buffering agents, such as tris-hydroxymethyl amino-methane (THAM), carbicarb, and dichloroacetate (DCA) have not shown any clinical benefit in patients with lactic acidosis. Carbicarb and DCA are unavailable in the United States. THAM can bind to both CO₂ and metabolic acids. Protonated THAM is excreted by the kidney through glomerular filtration together with bicarbonate or another anion. Thus, THAM can increase the buffering capacity of blood without generating CO₂ but is less effective in patients with anuria. Reported toxicities of THAM include hyperkalemia, hypoglycemia, and respiratory depression.⁹ THAM has not been specifically evaluated as a therapeutic agent for lactic acidosis in clinical trials. Carbicarb, an equimolecular mixture of sodium bicarbonate and sodium carbonate, has a buffering capacity similar to sodium bicarbonate but generates less CO₂. Animal studies have demonstrated inconsistent benefits of carbicarb in lactic acidosis, and one human study comparing the effects of sodium bicarbonate with carbicarb in metabolic acidosis found no benefit.²⁹⁻³¹ DCA stimulates the activity of mitochondrial PDH enzyme complex indirectly through inhibition of the PDH kinase and hence decreases lactate production. Data from animal studies and one placebo-controlled double-blind clinical trial demonstrated that DCA improved acid-base status but not hemodynamics or survival.^{28,32}

Dialysis can be theoretically used to treat lactic acidosis as it provides bicarbonate, removes lactate, prevents decreased ionized calcium, avoids volume overload, and removes drugs associated with lactic acidosis such as metformin.^{9,27} However the same potential risks of worsening lactic acidosis with bicarbonate administration through the dialysate exist. Furthermore, in severe lactic acidosis, the quantity of lactate cleared by dialysis is much less than the quantity of lactate generated. Continuous dialysis modalities are preferred over intermittent dialysis in hemodynamically unstable patients, and it can deliver bicarbonate at a lower rate. Evidence supporting intermittent or continuous dialysis for treatment of lactic acidosis is anecdotal at best, and prospective controlled trials are warranted.²⁷

D-Lactic Acidosis

D-lactic acidosis is an uncommon form of lactic acidosis that occurs in patients with jejunoileal bypass, small bowel resection, or other causes of short bowel syndrome due to bacterial overgrowth. In these patients, abnormally large amounts of glucose and starch are metabolized to D-lactic acid by gram-positive intestinal anaerobes such as *Lactobacilli*.^{33,34} D-lactic acid is then absorbed into the systemic circulation and causes acidemia that tends to persist since D-lactate is not recognized by L-lactate dehydrogenase, the enzyme that converts L-lactate into pyruvate. Patients typically present with recurring episodes of metabolic acidosis following a carbohydrate meal and neuro-

logic abnormalities including confusion, ataxia, slurred speech, and memory loss.³⁵ The diagnosis can be easily missed because the D-isomer responsible for the acidosis is not detected by the standard assay for lactate and requires a special assay for detection. Therapy for D-lactic acidosis includes administration of sodium bicarbonate to correct the acidosis, oral antibiotics to decrease gram-positive anaerobic colonic bacteria, and a low-carbohydrate diet to reduce carbohydrate delivery to the colon. D-lactic acidosis has also been described in patients who have large amounts of propylene glycol and in those with diabetic ketoacidosis (DKA).^{36,37}

Ketoacidosis

Ketoacidosis is a common complication in patients with insulin-dependent diabetes mellitus but can also be seen in chronic alcoholism and starvation (see Box 104-2). It results from the overproduction of ketone bodies, leading to accumulation of ketones in the plasma (ketonemia) and urine (ketonuria).

Diabetic Ketoacidosis

DKA occurs in patients with insulin-dependent diabetes mellitus and results from severe insulin deficiency in the setting of increased metabolic demand, such as from a concurrent infection or myocardial infarction. It can also occur from poor compliance with insulin or missed injections. Insulin deficiency results in decreased glucose uptake, glycogen store depletion, lipolysis, and fatty acid oxidation with increased ketoacid production (acetoacetate and beta-hydroxybutyrate). Symptoms can progress from polydipsia, polyuria, nausea, vomiting, dyspnea, and diffuse abdominal pain to confusion, lethargy, and somnolence. Laboratory findings include hyperglycemia, increased serum AG, ketonemia, ketonuria, and increased plasma osmolality. The diagnosis is established by measuring plasma and urine ketone levels. However, clinicians must be aware that the nitroprusside reaction used in standard plasma and urine tests only measures acetone and acetoacetate levels and not beta-hydroxybutyrate levels, which is the predominant ketone in severe untreated DKA. Therefore, laboratory analysis for ketones may be falsely negative. High plasma glucose levels can cause dilutional hyponatremia since the osmotic effect of hyperglycemia causes the movement of water into the intravascular space. For each 100 mg/dL of glucose over 100 mg/dL, the plasma sodium level is lowered by approximately 1.6 mEq/L. In spite of severely depleted total body potassium from osmotic diuresis, plasma potassium levels are initially elevated or within the normal range from insulin deficiency.^{38,39}

The major goals of treatment are rapid volume expansion, correction of hyperglycemia, correction of acid-base and electrolyte disturbances, and identification and treatment of the precipitating cause such as infection. Adults should initially receive a rapid infusion of 1 L of isotonic saline with repeat boluses as necessary to prevent hemodynamic collapse. When the blood pressure and heart rate have stabilized and the patient is euvolemic, isotonic saline can be switched to 0.45% saline at a slower rate to replace the free water lost by osmotic diuresis. Insulin is typically administered as a 10- to 20-unit intravenous (IV) bolus (0.15 units/kg) followed by an infusion of 5 to 7 units/hour (0.1 unit/kg/hour). Insulin inhibits lipolysis and gluconeogenesis and allows for the conversion of ketones to bicarbonate. If the blood sugar falls below 250 mg/dL, the rate of insulin should be decreased to 0.03 u/kg/hour. Once the AG normalizes, subcutaneous insulin should be administered while the insulin infusion is continued for another 1 to 2 hours. When blood sugar is less than 200 to 250 mg/dL, 5% to 10% dextrose should be added to the fluids. Potassium replacement should be administered at 10 to 20 mEq/hour if the plasma potassium level is less than 5.3 mEq/L and if renal failure is not present. Plasma potassium levels should be measured frequently, and the infusion should be stopped if hyperkalemia occurs. Small amounts of IV sodium bicarbonate should only be administered if the arterial pH is less than 6.9, with frequent monitoring of pH and serum AG. Intravenous phosphate replacement can be given if the initial level is less than

1.0 mg/dL. Plasma phosphorus levels can be high initially due to the transcellular shift of phosphate out of the cell in the setting of acidosis and insulin deficiency.^{38,40}

Hemodialysis-dependent patients with DKA are managed differently. Insulin administration is frequently the only treatment needed for DKA management in these patients. Dialysis patients usually present with signs of extracellular volume expansion rather than volume depletion since osmotic diuresis cannot occur in the absence of kidney function. Therefore, dialysis patients do not require IV fluids unless they have evidence of extracellular fluid loss such as vomiting, diarrhea, or excessive insensible losses. If volume depletion is present, small amounts of isotonic saline should be carefully administered with close monitoring of respiratory and hemodynamic parameters. When volume overload is apparent, immediate hemodialysis is the therapy of choice. Dialysis-dependent patients with DKA should not receive routine potassium supplementation since total body potassium stores may be high and patients are unable to excrete a potassium load. Urgent dialysis is indicated if hyperkalemia is present with electrocardiographic findings. Similarly, significant metabolic acidosis can only be corrected by hemodialysis.⁴⁰

Alcoholic Ketoacidosis

Alcoholic ketoacidosis (AKA) occurs in the setting of chronic alcoholism, recent binge drinking, minimal oral intake, and persistent vomiting. It is characterized by elevated plasma ketone levels, high AG, and normal or only slightly elevated plasma glucose level. Prolonged starvation results in decreased insulin activity, glycogen depletion, increased counterregulatory hormone production, dehydration, and increased lipolysis and fatty acid oxidation with accumulation of ketoacids. The metabolism of ethanol itself promotes ketoacidosis by leading to an accumulation in reduced NADH. Reduced NADH then results in impaired conversion of lactate to pyruvate, preferential conversion of pyruvate to lactate, and a shift toward beta-hydroxybutyrate production. Beta-hydroxybutyrate is the predominant ketone in AKA. The standard nitroprusside test for detecting ketones only detects acetoacetate and may be falsely negative or only minimally positive in AKA, leading to an underestimation of the degree of ketoacidosis.^{41,42}

Patients with AKA frequently present with a mixed acid-base disturbance. They can have elevated AG metabolic acidosis from ketoacidosis and lactate, metabolic alkalosis from persistent vomiting, and chronic respiratory alkalosis from liver disease. Magnesium and phosphate levels may be low due to increased urinary excretion and poor nutrition.

The mainstay of treatment is hydration with 5% dextrose in isotonic saline. Before glucose administration, thiamine should be given to avoid precipitating Wernicke encephalopathy. Carbohydrate and fluid replacement reverse the pathophysiologic derangements that lead to AKA by increasing plasma insulin levels and suppressing the release of glucagon and other counterregulatory hormones. Dextrose stimulates the oxidation of NADH and aids in normalizing the NADH/NAD⁺ ratio. Insulin should be avoided since it can lead to hypoglycemia, especially as the patient's endogenous insulin levels rise with carbohydrate and fluid repletion. Bicarbonate is only recommended if the plasma pH is less than 7.1 and the acidosis is not responding to IV fluids. Hypophosphatemia, hypokalemia, and hypomagnesemia should be corrected. Glucose infusion can exacerbate hypophosphatemia, resulting in rhabdomyolysis if not repleted.⁴³

Starvation Ketoacidosis

Starvation, as mentioned above, results in ketoacidosis due to the increase in counterregulatory hormones and a decrease in insulin level, promoting fatty acid oxidation, gluconeogenesis, and ketone production. However, in comparison to the potentially severe ketoacidosis that develops in uncontrolled diabetes and alcoholic states, ketoacid levels do not typically exceed 10 mEq/L with fasting. This is probably due to the insulin level, which, though lower, is still enough to limit the production of free fatty acids and thus ketoacidosis.^{44,45}

Toxin-Induced

See Boxes 104-2 and 104-3.

Toxic Alcohol Ingestions

Accumulation of the metabolites of methanol, ethylene glycol, diethylene glycol, and propylene glycol cause a high AG and increased plasma osmolal gap. Intoxication should be suspected in any patient who presents with high-AG metabolic acidosis, renal failure, and neurologic findings, and treatment should be initiated early.

The normal range of plasma osmolality is 285 to 290 mOsm/kg. Plasma osmolality can be estimated from the following formula:

$$\text{Calculated Posm} = (2 \times \text{plasma [Na]}) + (\text{glucose, in mg/dL})/18 + (\text{blood urea nitrogen, in mg/dL})/2.8$$

The plasma osmolal gap represents the difference between the measured and calculated plasma osmolality. A difference of higher than 10 mOsm/kg is considered an osmolal gap. Accumulation of the above alcohols will typically produce an osmolal gap of higher than 20 mOsm/kg. Methanol gives rise to the greatest increment in plasma osmolality, followed by ethylene glycol, propylene glycol, and finally diethylene glycol.⁴⁶ The absence of an osmolal gap does not exclude an alcohol-related intoxication. Furthermore, although the plasma osmolal gap may support the diagnosis of ingestion of a toxic alcohol, plasma toxicology screens specifically looking for the toxins are considered as the gold standard.

Other causes of high-AG metabolic acidosis that can be associated with an elevated plasma osmolal gap include lactic acidosis, ketoacidosis, advanced chronic kidney disease (CKD), formaldehyde ingestion, and paraldehyde ingestion. The plasma osmolal gap is usually less pronounced in these disorders (≤ 15 –20 mOsm/kg), and such testing is not typically performed. Substances that can cause an osmolal gap without metabolic acidosis are ethanol, isopropyl alcohol ingestion, infusion of nonconductive glycine, sorbitol or mannitol solutions, severe hyperproteinemia, and severe hyperlipidemia.⁴⁶

Methanol, used as a laboratory and industrial solvent, is commonly found in windshield-wiper fluid, deicing products, gas-line antifreeze, and various paint solvents and thinners. It is metabolized by alcohol dehydrogenase (ADH) to formaldehyde, which is further metabolized by aldehyde dehydrogenase (ALDH) to formic acid. The most common symptoms of methanol intoxication are abdominal pain and visual disturbances, including decreased visual acuity, photophobia, and blurred vision. Formic acid is the main toxic metabolite responsible for retinal, ophthalmic, and neural toxicity. Permanent blindness may occur due to optic nerve atrophy. High-AG metabolic acidosis is due to generation of formic acid and increased production of lactic acid. Lactic acidosis results from impaired cellular respiration by formate or increased generation of NADH during the metabolism of methanol.^{46,47}

Ethylene glycol is typically found in radiator antifreeze as well as various solvents and paint formulations. It is metabolized by ADH to glycoaldehyde, then by ALDH to glycolic acid, which is further metabolized to glyoxylic acid and finally oxalic acid. The metabolites are responsible for neurologic, cardiopulmonary, and renal toxicity. Typically, neurologic abnormalities occur initially, followed by cardiopulmonary dysfunction, and finally renal dysfunction. Neurologic findings include coma, seizures, meningism, external ocular paralysis, and delayed onset of cranial nerve deficits. Cardiopulmonary findings include tachycardia, hyperventilation, and heart failure. Oxalic acid combines with plasma calcium to form calcium oxalate, which leads to hypocalcemia, QTc prolongation, and risk of ventricular arrhythmias. Calcium oxalate crystals precipitate in the renal tubules, causing flank pain, oliguria, and renal failure. Calcium oxalate crystals are present in the urine 4 to 8 hours after ingestion of ethylene glycol. High-AG metabolic acidosis is due to generation of glycolic, glyoxylic, and oxalic acids and increased production of lactic acid. Measurement of plasma ethylene glycol levels can confirm poisoning.^{46,47}

Methanol and ethylene glycol poisoning are treated with fomepizole or ethanol, which inhibits ADH and prevents the formation of toxic

metabolites. Fomepizole (15 mg/kg loading dose, then 10 mg/kg every 12 hours) is preferred over ethanol due to its easier dosing regime and better side effect profile. The indications for antidotal therapy are a plasma concentration of methanol or ethylene glycol higher than 20 mg/dL and two of the following: osmolal gap higher than 10 mOsm/kg, arterial pH lower than 7.3, plasma bicarbonate level lower than 20 mEq/L, and presence of urinary oxalate crystals. Indications for hemodialysis are severe metabolic acidosis (pH < 7.25), visual abnormalities, renal failure, electrolyte abnormalities not responsive to treatment, hemodynamic instability despite ICU treatment, and plasma concentration higher than 50 mg/dL. In ethylene glycol toxicity, pyridoxine and thiamine are administered to increase the metabolism of glycolic and glyoxylic acid to the less toxic metabolites glycine and alpha-hydroxy-beta-ketoadipate. In methanol toxicity, folic acid or folinic acid increases the breakdown of formic acid to CO₂ and water.^{46,47}

Diethylene glycol is present in brake fluid and is used as an illegal adulterant in ethanol spirits or in medication. Diethylene glycol is oxidized by ADH to 2-hydroxyethoxyacetaldehyde and then via ALDH to 2-hydroxyethoxyacetic acid. Acute oliguric and nonoliguric renal failure are frequent. Treatment consists of hemodialysis and fomepizole.⁴⁶

Propylene glycol is a solvent for unstable drugs including benzodiazepines, phenytoin, nitroglycerine, and some topical medications. The majority of intoxications have resulted from excessively large or rapidly infused intravenous injections of propylene glycol-containing medications such as benzodiazepines. Neurologic depression is the primary manifestation of acute propylene glycol poisoning. Metabolic acidosis is attributed to generation of lactic acid during metabolism of propylene glycol. Discontinuation of propylene glycol-containing medication can lead to correction of the acidosis within 24 hours in most patients. In the face of extremely high blood concentrations, hemodialysis is extremely effective in rapidly reducing plasma propylene glycol levels.⁴⁶

Use of isopropyl alcohol is the most common cause of toxic alcohol exposure in the United States; it is found in rubbing alcohol, hand sanitizer gels, and other antiseptic preparations. It is metabolized by ADH to acetone, without production of AG acidosis. Toxicity is mainly limited to gastrointestinal (GI) effects, such as hemorrhagic gastritis and neurologic depression. Isopropyl alcohol is the only toxic alcohol that causes ketosis without acidosis. In comparison to other toxic alcohols, isopropanol intoxication is usually managed supportively. Hemodialysis may increase the rate of elimination of both isopropyl alcohol and acetone and should be considered for patients with deteriorating mental status or hemodynamic instability.⁴⁶

Salicylates

Salicylate toxicity may develop with either acute or chronic exposure to salicylates. Acute and chronic salicylate toxicity is associated with a high mortality if not recognized early and treated. Salicylates are found in over-the-counter medications such as aspirin, bismuth subsalicylate, effervescent antacids, ointments, liniments, and oil of wintergreen (methyl salicylate) as well as in numerous prescription medications. Patients with salicylate toxicity may present with neurologic symptoms (cerebral edema, coma, agitation, tinnitus, or seizures), pulmonary symptoms (hyperventilation/tachypnea or acute lung injury) and GI symptoms (nausea or vomiting). Nausea, vomiting, diaphoresis, and tinnitus are the earliest signs and symptoms of salicylate toxicity. Salicylates stimulate the respiratory center, leading to hyperventilation and respiratory alkalosis. They also uncouple oxidative phosphorylation and interfere with the Krebs cycle, leading to increased lactate production, ketosis, and high-AG metabolic acidosis. Interference with aerobic respiration also causes hypoglycemia, fever, and fluid loss. Adult patients with acute poisoning usually present with mixed respiratory alkalosis and metabolic acidosis but can also present with primary respiratory alkalosis. In children, respiratory alkalosis may be transient, with metabolic acidosis occurring early in the course.⁴⁸

The therapeutic range of salicylates is 10 to 30 mg/dL. Patients become symptomatic at concentrations higher than 40 mg/dL. Levels

higher than 90 to 100 mg/dL usually have serious or life-threatening toxicity. In overdoses, the peak plasma concentration may not occur for 4 to 6 hours. A 6-hour salicylate level higher than 100 mg/dL is considered lethal and is an indication for hemodialysis. Labs should be repeated every 4 to 6 hours until the level falls into the nontoxic range. Renal excretion of salicylic acid depends on urinary pH. Increasing the urine pH to 7.5 prevents reabsorption of salicylic acid from the urine. Since acidosis facilitates transfer of salicylate into tissues, especially in the brain, it must be treated aggressively by raising the blood pH higher than the brain pH, thereby shifting the equilibrium from the tissues to the plasma. Alkalinization with IV sodium bicarbonate is the mainstay of treatment in patients whose plasma pH is not already elevated (>7.5), and care should be taken not to raise plasma pH to inappropriately high levels (>7.55). Hypokalemia occurs commonly in salicylate-poisoned patients and prevents urinary excretion of salicylate unless corrected. Since intoxication can decrease cerebral glucose concentrations despite normal plasma glucose concentrations, adults who are hypoglycemic or have altered mental status, regardless of their plasma glucose concentration, should be treated with supplemental glucose. Indications for hemodialysis include a plasma level higher than 120 mg/dL (acutely) or higher than 100 mg/dL (6 hours post ingestion), refractory acidosis, coma or seizures, noncardiogenic pulmonary edema, volume overload, and renal failure. In chronic overdose, hemodialysis may be required for a symptomatic patient with a plasma salicylate level higher than 60 mg/dL.^{48,49}

Pyroglutamic Acidosis

Accumulation of 5-oxoproline (pyroglutamic acid), an organic acid intermediate of the gamma-glutamyl cycles, is a rare, but underdiagnosed, cause of severe, high-AG metabolic acidosis in adults. The acidemia associated with pyroglutamic acid usually occurs in association with acetaminophen therapy and in the setting of severe sepsis or liver or renal dysfunction. Heterozygosity for glutathione synthase deficiency may also be an underlying risk factor for development. The etiology appears to be a drug-induced reversible inhibition of either glutathione synthetase or 5-oxoprolinase. Diagnosis is made by measuring urinary 5-oxoproline levels to demonstrate the presence of pyroglutamic acid. Treatment with *N*-acetylcysteine to replenish glutathione should be considered.⁵⁰⁻⁵²

Renal Failure

Early CKD is associated with hyperchloremic normal AG metabolic acidosis, while end-stage renal disease (uremia) is associated with elevated AG metabolic acidosis. In early CKD, acid excretion is initially maintained by increased ammonium excretion. When the glomerular filtration rate (GFR) falls below 40 to 50 mL/min, tubular function decreases, leading to retention of H⁺, an increase in the amount of bicarbonate excreted, and metabolic acidosis. To maintain electroneutrality, the kidneys retain chloride with each bicarbonate ion lost, causing hyperchloremic metabolic acidosis. Since glomerular function decreases at a much slower rate than the loss of tubular function, the excretion of sulfate and other organic and inorganic acid anions is not affected as their filtration by the kidney is maintained. The AG remains in normal range due to the continued excretion of organic acids by the kidneys. In advanced CKD, when the GFR falls below 20 mL/min, the capacity of the kidneys to filter the anions of organic acids is significantly diminished, causing retention of phosphates, sulfates, urate, and hippurate anions in the plasma and development of elevated AG metabolic acidosis.^{53,54}

Clinical consequences of chronic metabolic acidosis in CKD include osteopenia, worsening secondary hyperparathyroidism, CKD progression, and increased mortality. Recent clinical trials have suggested that correction or prevention of metabolic acidosis by alkali administration is able to slow progression of CKD. As a result, to prevent CKD progression and bone loss, sodium bicarbonate supplementation (0.5-1 mEq/kg/day) is recommended for patients with CKD having plasma bicarbonate concentrations lower than 22 mEq/L.⁵⁴

NONANION GAP (HYPERCHLOREMIC) METABOLIC ACIDOSIS

Normal or non-AG metabolic acidosis is also called *hyperchloremic metabolic acidosis* because the kidneys reabsorb chloride instead of bicarbonate, yielding no net change in the serum AG. Hyperchloremic metabolic acidosis may result from impaired renal acid excretion, increased renal or GI bicarbonate loss, H⁺ gain, marked urinary excretion of organic acid anions with replacement with chloride, or administration of chloride-rich solutions during resuscitation (Box 104-4). In impaired renal acid excretion, the absence of sufficient ammonium excretion results in the acid anions being excreted with sodium and potassium. This results in a sodium deficit and avid renal retention of filtered sodium and chloride. The retained chloride replaces the lost bicarbonate. GI or urinary bicarbonate loss leads to a sodium deficit and a reduction in extracellular fluid volume. This stimulates renal retention of sodium and chloride, thereby replacing the lost bicarbonate by the retained chloride.⁵⁵

Urinary Anion Gap

In assessing the cause of hyperchloremic metabolic acidosis, the urine AG (UAG) may be useful in differentiating renal causes from GI

causes. The UAG is calculated as the difference between the measured urine cations (Na⁺ and K⁺) and urine Cl[−]:

$$\text{UAG} = (\text{Na}^+) + (\text{K}^+) - (\text{Cl}^-)$$

In diarrhea and other nonrenal causes of hyperchloremic acidosis, the kidney should attempt to compensate by increasing net acid excretion. The major mechanism for this increase is a marked increase in urinary ammonium excretion. Since urinary ammonium measurements are not readily available, the UAG serves as a surrogate. Under normal circumstances, the sum of the excreted urine sodium and urine potassium is greater than the amount of excreted urine chloride. Therefore, the UAG has a positive value in healthy individuals. In patients with normal AG metabolic acidosis, the excretion of ammonium occurs with chloride, increasing the urine chloride concentration. In such settings, urine chloride usually exceeds the sum of urine sodium and urine potassium, resulting in a negative UAG; the UAG will be negative when ammonium is present and balanced by negatively charged urinary chloride. A negative UAG is consistent with increased ammonium excretion and occurs in patients who develop metabolic acidosis as a result of diarrhea. If there is little ammonium present, the UAG will be zero or positive, similar to that in patients who have hyperchloremic metabolic acidosis associated with impaired ammonium excretion, as seen in renal tubular acidosis (RTA).

There are several limitations to the UAG. The UAG cannot be interpreted accurately in the setting of increased urinary excretion of unmeasured anions. Unmeasured anions may be excreted with sodium or potassium or with ammonium. Examples of unmeasured urinary anions include ketoacids, hippurate, D-lactate, and 5-oxoproline. As a result, the excretion of ammonium with these unmeasured anions will not reduce the UAG, which occurs when ammonium is excreted with chloride. In addition, the excretion of sodium or potassium with unmeasured anions leads to a positive UAG.⁵⁶ The UAG also cannot be interpreted in volume-depleted states with urine sodium levels less than 25 mEq/L due to impaired distal sodium delivery.⁵⁷

The urine osmolal gap (UOG) can overcome some of the limitations of the UAG.⁵⁶ The UOG indirectly assesses urine ammonium concentration by comparing the directly measured urine osmolality to the calculated urine osmolality. The formula for calculating urine osmolality is as follows:

$$\begin{aligned} \text{Calculated urine osmolality (mOsm/kg)} \\ = (2 \times [\text{Na} + \text{K}]) + (\text{urea nitrogen in mg/dL})/2.8 \\ + (\text{glucose in mg/dL})/18 \end{aligned}$$

The UOG is the difference between the directly measured osmolality and the calculated urine osmolality. Besides sodium, potassium, urea, and glucose (if present in the urine), the major urinary solute that contributes to urine osmolality is ammonium. Most of the UOG is, therefore, made up of ammonium in the form of ammonium chloride as well as ammonium excreted with other unmeasured anions. Thus, the UOG detects ammonium excretion regardless of the anion that is excreted along with it. The UOG must be divided by two in order to account for the anion being excreted with ammonium. In the setting of metabolic acidosis, urine ammonium levels should be higher than 200 mEq/L. An ammonium urine concentration of less than 75 mEq/L in a patient with metabolic acidosis indicates impaired renal ammonium excretion and correlates with a UOG of less than 150 mOsm/kg. In the setting of hyperchloremic metabolic acidosis from GI causes such as diarrhea, the UOG should be higher than 400 mOsm/kg.^{55,56}

Renal Tubular Acidosis

RTA is characterized by impaired urinary acidification, resulting in retention of H⁺, reduction in plasma bicarbonate levels, and hyperchloremic normal AG metabolic acidosis. RTA can be classified as proximal (type 2), distal (type 1), and hyperkalemic (type 4). The UAG is usually positive in RTA due to an inability to excrete H⁺. Proximal (type 2) and

*See source for complete list of disorders.

distal (type 1) RTA are uncommon disorders. See Boxes 104-4 and 104-5.

Proximal Renal Tubular Acidosis (Type 2)

Proximal RTA is characterized by impaired proximal bicarbonate reabsorption with a lowered threshold for bicarbonate reclamation. This results in renal bicarbonate wasting whenever the bicarbonate concentration exceeds this lowered threshold. Below this threshold, bicarbonate is conserved, and maximal urinary acidification (urine $\text{pH} < 5.5$) occurs. Bicarbonate loss in the urine leads to increased H^+ concentration in the blood and a subsequent reduction in the arterial pH . Because of impaired proximal bicarbonate reabsorption, the distal nephrons become overwhelmed by an increase in bicarbonate delivery and cannot compensate for the loss in proximal function. However, as the plasma bicarbonate level decreases to 15 to 18 mEq/L , the amount of filtered bicarbonate decreases with reduced delivery of bicarbonate to the distal nephrons. At that point, the distal nephrons are able to function, leading to a reduction in bicarbonate loss and appropriate acidification of the urine to a pH less than 5.5. These patients also have hyperaldosteronism from salt wasting due to the defect in proximal reabsorption of filtered bicarbonate. Because of

hyperaldosteronism, urinary potassium wasting and hypokalemia are common.^{55,58}

Proximal RTA is diagnosed by measurement of the urine pH and fractional bicarbonate excretion during bicarbonate infusion. Intravenous sodium bicarbonate is infused at a rate of 0.5 to 1.0 mEq/kg/hour to increase the plasma bicarbonate concentration toward normal (18–20 mEq/L). The urine pH , even if initially acidic, will rise rapidly once the reabsorptive threshold for bicarbonate is exceeded. As a result, the urine pH will increase to higher than 7.5, and the fractional excretion of bicarbonate will exceed 15%.^{55,58}

In adults, proximal RTA is typically secondary to acquired proximal tubular damage such as heavy metal exposure and multiple myeloma, while in children, it is associated with metabolic defects (see Box 104-5). Proximal RTA is often accompanied by other proximal tubular transport defects including renal glycosuria, phosphate wasting, aminoaciduria, and hypouricemia (Fanconi syndrome). Medications such as carbonic anhydrase inhibitors (e.g., acetazolamide) and topiramate can cause proximal RTA by impairing proximal bicarbonate reabsorption without affecting the reabsorption of other proximal tubule solutes. The drugs tenofovir and ifosfamide can cause Fanconi syndrome.⁵⁵

Complications include bone disease due to an increase in bone buffering of excess acid and acquired vitamin D deficiency from decreased calcitriol production. Defects in proximal transport may also result in phosphate wasting and hypophosphatemia, leading to rickets in children and osteomalacia or osteopenia in adults.^{55,58}

Standard treatment is with oral alkali therapy. Since exogenous alkali is rapidly excreted in the urine, considerably higher doses of alkali are required as in comparison to distal and type 4 RTA. About 10 to 15 mEq/kg/day of alkali is typically required to stay ahead of urinary excretion. Potassium citrate is the preferred form of alkali to help with potassium losses. Thiazides are also sometimes used in conjunction with a low-salt diet to reduce the amount of alkali required. Thiazides induce volume contraction and enhance proximal bicarbonate reabsorption.⁵⁸

Classic Distal Renal Tubular Acidosis (Type 1)

Classic distal RTA results from defective H⁺ secretion in the distal tubule. Impaired H⁺ secretion results in an inability to acidify the urine pH beyond 5.5 and reduced net acid excretion. The plasma bicarbonate may fall below 15 mEq/L. Hypokalemia occurs due to urinary potassium wasting from increased potassium secretion by distal tubular cells in the setting of diminished H⁺ secretion. Hypercalciuria, alkaline urine, and low urinary citrate levels promote the precipitation of calcium phosphate stones and nephrocalcinosis. A diagnosis is made by the findings of hypokalemia, normal AG metabolic acidosis, inappropriately high urine pH (>5.5) regardless of the plasma bicarbonate concentration, and a positive UAG.⁵⁸

The most common causes in adults are autoimmune disorders such as Sjögren's syndrome. In children, RTA is most often a primary hereditary condition (see Box 104-5). Drugs such as ifosfamide and amphotericin cause distal RTA in adults and children. Complications include failure to thrive, rickets, and stunting of growth in children and osteomalacia or osteopenia in adults. Patients may otherwise be asymptomatic or may present with symptoms of severe acidosis or hypokalemia.⁵⁸

Adults are generally treated with oral sodium bicarbonate or sodium citrate 1 to 2 mEq/kg/day. Patients with significant hypokalemia, nephrolithiasis, or nephrocalcinosis are treated with potassium citrate or Polycitra (potassium citrate plus sodium citrate).

Hyperkalemic Distal Renal Tubular Acidosis (Type 4)

Hyperkalemic distal RTA is characterized by hyperkalemia and hyperchloremic metabolic acidosis. It can occur in the setting of aldosterone deficiency or resistance or due to a voltage-dependent defect in H⁺ secretion. In aldosterone deficiency or resistance, hyperkalemia is the primary disturbance, suppressing proximal tubular ammonium production and producing metabolic acidosis.⁵⁹ Urinary acidification is intact. The metabolic acidosis seen is generally mild, with the plasma bicarbonate level usually higher than 15 mEq/L. Despite impaired distal H⁺ secretion, the urine pH is generally below 5.5. The ability to acidify the urine in this condition is due to the inadequate amount of ammonia available for buffering of protons since the urinary pH falls in the absence of buffers. The findings of hyperkalemic, normal AG metabolic acidosis with an appropriately low urine pH (<5.5) and positive UAG confirm the diagnosis. The diagnosis is further supported by a bicarbonate fractional excretion of higher than 10% in the setting of bicarbonate infusion.⁵⁸

Hyporeninemic hypoaldosteronism is the most common cause of type 4 RTA in patients with mild to moderate renal insufficiency due to diabetic nephropathy (see Box 104-5). Many drugs can cause type 4 RTA by affecting renin release, aldosterone production, or tubular potassium excretory capacity. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit renin release. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), calcineurin inhibitors, and heparin can all reduce aldosterone production. Inhibitors of tubular potassium excretion include spironolactone, eplerenone, triamterene, and amiloride. The tubulointerstitial diseases commonly

associated with type 4 RTA include sickle cell disease and obstructive nephropathy.^{58,59}

Hyperkalemia from aldosterone deficiency or resistance can be diagnosed by measuring the transtubular potassium gradient (TTKG)^{59,60}:

$$\text{TTKG} = \frac{(\text{urine K}^+ \times \text{plasma osmolality})}{(\text{plasma K}^+ \times \text{urine osmolality})}$$

A TTKG higher than 8 indicates that aldosterone is present and that the collecting duct is responsive to it. A TTKG less than 5 in the presence of hyperkalemia indicates aldosterone deficiency or resistance. For the test to be accurate, the urine sodium concentration should be higher than 10 mEq/L and the urine osmolality should be greater than or equal to the plasma osmolality.⁶⁰

Therapy is aimed at reducing the plasma potassium concentration and includes volume expansion, dietary potassium restriction, and potassium-wasting diuretics. Acidosis will usually improve once the hyperkalemic impedance of ammonium production is removed. Any drugs that suppress or block aldosterone should be discontinued. Mineralocorticoid replacement with fludrocortisone will improve hyperkalemia and acidosis but is not appropriate with patients having hypertension or a history of heart failure. These patients are instead treated with a low potassium diet and a loop diuretic.⁵⁹

Gastrointestinal Tract Loss

The secretions of the large and small bowel are mostly alkaline and have a bicarbonate level higher than that in the plasma. Significant loss of lower GI secretions results in non-AG metabolic acidosis (see Box 104-4). Diarrhea is the most common cause of external loss of bicarbonate resulting in non-AG metabolic acidosis. Other causes include external drainage of pancreatic or biliary secretions as from fistulas, ileus secondary to intestinal obstruction, and villous adenomas. Drugs that increase GI bicarbonate loss include calcium chloride, magnesium sulfate, and cholestyramine. Significant bicarbonate loss also occurs in patients who abuse laxatives. Urinary diversions, such as ureterosigmoidostomy or ureteroileostomy, can cause non-AG metabolic acidosis due to absorption of chloride in exchange for bicarbonate across the bowel mucosa. Absorption of urinary ammonium in the sigmoid colon may also contribute to the development of acidosis as metabolism of the ammonium in the liver results in production of H⁺.

Metabolic acidosis and hypokalemia from GI losses increase renal synthesis and ammonia excretion, thereby providing a urinary buffer that increases urine pH despite increased net acid excretion.⁵⁵ The urine pH is higher than 5.5 instead of an acid urine pH as expected with systemic acidosis. Metabolic acidosis due to GI losses with a high urine pH can be differentiated from RTA by calculating the UAG.

Other Causes of Nonanion Gap Acidosis

See Box 104-4.

Expansion of the extracellular-fluid volume with non-bicarbonate-containing solutions, such as isotonic saline, causes metabolic acidosis by diluting the previous existing plasma bicarbonate (dilutional acidosis) and increasing the chloride load. This increased chloride load exceeds the renal capacity to generate equal amounts of HCO₃⁻.^{55,61}

Amino acids in total parenteral nutrition (TPN) are metabolized to HCl, which causes a transient non-AG metabolic acidosis. The decreased pH and decreased HCO₃⁻ stimulate renal reabsorption and generation of HCO₃⁻. Metabolic acidosis occurs if the acid load overrides the ability of the renal tubules to secrete H⁺ and generate ammonia for excretion in the urine, usually a short-lived process.⁵⁹

In prolonged hypercapnia, renal tubules compensate for a prolonged respiratory alkalosis by decreasing reclamation and generation of HCO₃⁻ (which takes 12-24 hours for full affect). If the respiratory alkalosis resolves rapidly, reclamation and generation of HCO₃⁻ will return to normal over 1 to 2 days. During this period a resolving non-AG metabolic acidosis occurs.

In toluene intoxication or the treatment phase of DKA, metabolic acid production is markedly increased. Although ammonium excretion is also increased, the rate of urinary excretion of the acid anions (hippurate and ketoanion, respectively) exceeds the excretion of ammonium. The anions not excreted with ammonium are excreted with sodium and potassium, causing sodium deficits and avid retention of filtered sodium and chloride. The lost bicarbonate is replaced by the retained chloride. In addition, administration of large volumes of isotonic saline for resuscitation in patients with DKA promotes diuresis with continued urinary loss of ketone bodies with sodium as the cation while delivering chloride to replace the lost ketoanions.^{55,59}

METABOLIC ALKALOSIS

Primary metabolic alkalosis is a subset of acid-base disorders characterized by an elevation in blood arterial pH, an increase in plasma HCO_3^- concentration, and a compensatory hypoventilation, resulting in a rise in Paco_2 . It is encountered relatively frequently in clinical practice as a result of loss of H^+ from the GI tract or urine. This disorder is also often accompanied by hypochloremia and hypokalemia.⁶²

In the presence of an increased serum bicarbonate concentration and low serum chloride (Cl^-) concentration, a patient may have either metabolic alkalosis or chronic respiratory acidosis. These disorders can be differentiated by the arterial pH, which is increased (>7.4) in metabolic alkalosis and decreased (<7.4) or normal in chronic respiratory acidosis. In primary metabolic alkalosis, the Paco_2 generally increases approximately 6 to 7.5 mm Hg for every 10 mEq/L increase in HCO_3^- above normal.

Metabolic alkalosis may occur as a simple disorder or, when associated with other disorders like respiratory acidosis, respiratory alkalosis, or metabolic acidosis, as a mixed disorder. An increase in the serum AG may be the only sign that metabolic acidosis coexists with metabolic alkalosis. Clinical examples of a mixed AG acidosis and metabolic alkalosis include patients with both DKA and vomiting, or lactic acidosis with vomiting.⁶³

Pathogenesis

Metabolic alkalosis can result from the loss of H^+ , transcellular H^+ shift, exogenous alkali administration, or contraction alkalosis. These factors may initiate systemic alkalosis, but under normal physiologic circumstances, alkalosis should never develop because the kidney is efficient at removing excess bicarbonate. However, in conditions where kidney function may be compromised, bicarbonate excretion may become impaired. Metabolic alkalosis is typically associated with impairment in kidney function, which is thought to maintain the alkalosis.

In effect, metabolic alkalosis results from impaired bicarbonate elimination from the kidney by its regular mechanisms. An increase in the plasma bicarbonate concentration results from either exogenous HCO_3^- administration or endogenous production. The kidneys will preserve rather than eliminate excess alkali and maintain alkalosis, if either of the following conditions is present: (1) Cl^- deficiency (or extracellular volume contraction), typically accompanied by potassium (K^+) depletion, which reduces effective renal perfusion and glomerular filtration and enhances bicarbonate reabsorption. Alkalosis in this setting can usually be corrected with saline infusion (saline-responsive) and K^+ repletion; or (2) hypokalemia due to a mineralocorticoid excess, which is not responsive to extracellular volume expansion.⁶⁴⁻⁶⁶ This cause of alkalosis is not generally responsive to saline (saline-resistant), and treatment considerations include medications or surgical resection.

The most common factor maintaining metabolic alkalosis is a reduction in extracellular volume (ECV), which leads to a reduction in GFR and a subsequent increase in sodium (Na^+) and HCO_3^- reabsorption. Hypokalemia can both cause and maintain the presence of metabolic alkalosis. Mineralocorticoid excess is another factor that

may trigger metabolic alkalosis, and in those cases, hypokalemia is the factor that maintains the alkalosis.

Metabolic alkalosis associated with a reduction in volume responds well to repletion with normal (0.9%) saline and is known as saline-responsive. However, mineralocorticoid or hypokalemia-induced alkalosis does not generally respond to volume administration and is said to be saline-unresponsive.

Symptoms of Metabolic Alkalosis

The symptoms of metabolic alkalosis vary according to the severity of the underlying acid-base abnormality. Presenting symptoms are often similar to those of hypocalcemia and may include mental confusion, decreased consciousness, seizures, muscle cramping, tetany, paresthesia, cardiac arrhythmias, and dyspnea. Common electrolyte abnormalities associated with alkalosis include hypokalemia and hypophosphatemia.⁶⁷

Extracellular Fluid Volume Contraction, Hypokalemia, and Secondary Hyperaldosteronism

See Box 104-6.

Gastrointestinal Causes

GI hydrogen loss can result from the removal of gastric secretions (vomiting or nasogastric suction) or loss of intestinal secretions (congenital chloridorrhea, villous adenoma, laxative abuse). Loss of H^+ leading to metabolic alkalosis most commonly occurs through the GI tract by vomiting or nasogastric (NG) suction. Gastric fluid contains a high concentration of hydrochloric acid (HCl) and a lower concentration of potassium chloride (KCl). Each mEq of H^+ secreted generates 1 mEq of HCO_3^- , which is then absorbed into the plasma. Under normal physiologic conditions, the increase in plasma HCO_3^- concentration is only transient, as acid secretion into the duodenum stimulates an equal amount of pancreatic HCO_3^- secretion, which neutralizes the acid. However, if gastric fluid is removed by vomiting or NG suction, there is no stimulus for HCO_3^- secretion, since the HCl does not reach the duodenum. The net result is an increase in plasma HCO_3^- and subsequent metabolic alkalosis.

Under normal circumstances, any excess HCO_3^- generated would be excreted by the kidney in the urine, thereby correcting alkalosis. However, vomiting or NG suction also lowers the extracellular fluid compartment and effective circulating volume (ECV). The reduction in ECV leads to decreased GFR and less HCO_3^- filtered, and also stimulates angiotensin and aldosterone production (secondary hyperaldosteronism), leading to increased Na^+ and HCO_3^- reabsorption by the proximal tubules.⁶⁸ Increased Na^+ reabsorption leads to increased HCO_3^- reabsorption, because of the increase in H^+ secretion as Na^+ is exchanged for H^+ by the Na-H^+ transporter at the proximal tubule. Secreted H^+ ions combine with filtered HCO_3^- , causing reabsorption. Aldosterone primarily acts at the distal tubule to increase H^+ and K^+ secretion, resulting in greater acid and K^+ excretion. These processes lead to a hypokalemic metabolic alkalosis. Notably, the near complete reabsorption of HCO_3^- in the setting of reduced ECV leads to the paradoxical finding of an acidic urine, despite the presence of extracellular alkalosis.

Renal Causes

See Box 104-6. Contraction alkalosis occurs when there is a relatively large loss of bodily fluid that does not contain HCO_3^- . In this setting, which is most commonly due to diuretics, the extracellular volume contracts around a fixed amount of HCO_3^- , resulting in a rise in HCO_3^- concentration.⁶⁹ Note that in this situation, total body bicarbonate remains the same despite the concentration change. Chronic diuretic use generates alkalosis by increasing salt delivery to the distal tubule, with resulting stimulation of H^+ and K^+ secretion. Loop and thiazide diuretics may effectively lower extracellular volume without

GAIN-OF-FUNCTION MUTATION OF ENAC WITH EXTRACELLULAR FLUID VOLUME EXPANSION, HYPERTENSION, K^+ DEFICIENCY, AND HYPORENINEMIC HYPERALDOSTERONISM

Liddle's syndrome

Bartter's syndrome is a disorder characterized by impaired Cl^- absorption, which then leads to salt wasting, volume contraction, and activation of the renin-angiotensin system. Five types of Bartter's syndromes have been discovered with four inherited in an autosomal recessive manner.⁷⁰ Bartter's occurs more often in children, and the most common disorder results from a mutation of the gene encoding the bumetanide-sensitive $\text{Na}^+2\text{Cl}^-/\text{K}^+$ cotransporter (*NKCC2* or *BSC1*) on the apical membrane; however, other mutations have been found involving different transporter channels. Elevated prostaglandin levels have been reported with this disorder, likely from volume contraction, hypokalemia, or high angiotensin II levels.⁷¹ These defects lead to contraction of the extracellular volume, hyperreninemic hyperaldosteronism, increased Na^+ delivery to the distal nephron, subsequent with K^+ wasting and alkalosis. The differential diagnosis of Bartter's syndrome includes other causes of extravascular volume contraction, such as emesis, diuretic use, or laxative abuse. Inhibition of the renin-angiotensin-aldosterone system or the prostaglandin-kinin system has been the goal of current treatment, with medications like spironolactone, prostaglandin inhibitors, propranolol, and ACE inhibitors, but the utility of such agents has been limited. K^+ and magnesium (Mg^{++}) repletion are also an important part of therapy.

Gitelman's syndrome, like Bartter's syndrome, is autosomal recessive and may manifest with hypokalemia, volume depletion with secondary hyperreninemic hyperaldosteronism, normotension, or even low blood pressure. Gitelman's differs from Bartter's syndrome in that it occurs more often in adulthood and is characterized by hypocalciuria, hypermagnesuria, hypomagnesemia, similar to the effect of thiazide diuretics. Gitelman's syndrome occurs as the result of missense mutations in the gene *SLC12A3*, responsible for encoding the thiazide-sensitive distal convoluted tubule Na^+/Cl^- cotransporter (*NCCT*).^{70,72} Diminished activity of the Na^+/Cl^- cotransporter leads to calcium reabsorption and hypocalciuria. Reported symptoms include fatigue, cramping, nocturia, and salt craving. Treatment considerations include a sodium and potassium avid diet, with magnesium supplementation. ACE inhibitors have also been advocated for this disorder.

Hypokalemia is a frequent finding in patients with metabolic alkalosis. It is an important contributor to both the development and maintenance of the alkalosis. The underlying causes of metabolic alkalosis (e.g., vomiting, mineralocorticoid excess, diuretic use) induce both H^+ and K^+ loss and thus cause hypokalemia. However, hypokalemia itself can be a primary cause of metabolic alkalosis. Hypokalemia causes metabolic alkalosis by several mechanisms. Initially, hypokalemia causes a transcellular shift, where K^+ leaves and H^+ enters cells, thereby increasing extracellular pH. Hypokalemia also causes a transcellular shift in proximal tubule cells, resulting in intracellular acidosis and ammonium (NH_4^+) production and excretion. Finally, H^+ secretion increases in the proximal and distal tubules with hypokalemia, leading to further HCO_3^- reabsorption. The net effect is an increase in acid excretion.

Magnesium deficiency promotes distal H^+ secretion and acidification of urine by stimulating renin and aldosterone secretion, which result in hypokalemic alkalosis.

Posthypercapnic alkalosis is frequently overlooked as a complication of mechanical ventilation. The normal physiologic response to respiratory acidosis is a compensatory increase in HCO_3^- reabsorption by the kidney, which increases plasma HCO_3^- . Use of mechanical ventilation for this disorder may rapidly lower the Paco_2 ; however, plasma HCO_3^- will remain elevated, resulting in development of metabolic alkalosis.⁷³ The duration of alkalosis in this setting, however, is unclear. Chronic respiratory acidosis is thought to be associated with urine Cl^- loss, leading to hypovolemia and hypochloremia. Repletion of Cl^- and restoration of volume (usually with 0.9% saline) typically corrects this disorder. In posthypercapnic alkalosis, the rapid fall in Paco_2 may also lead to an acute increase in cerebral intracellular pH.^{74,75} Complications including neurologic abnormalities and death have been reported with this effect, and as a result most experts have recommended a gradual reduction in Paco_2 in patients with chronic hypercapnia.

concomitant loss of HCO_3^- , resulting in a net increase in serum HCO_3^- and contraction alkalosis. Alkalosis is then maintained by one of several mechanisms, such as reduction of the extracellular volume, hypokalemia, secondary hyperaldosteronism, or continued effect of the diuretic. Repletion of the extravascular fluid with 0.9% saline will typically improve the alkalosis in this setting.

Extracellular Volume Expansion and Mineralocorticoid Excess

The common causes of metabolic alkalosis maintain the alkalosis by hypovolemia-induced secondary hyperaldosteronism, which leads to increased acid excretion and hypokalemia. Disorders of mineralocorticoid excess, such as Conn's syndrome, Cushing's syndrome, and excess corticosteroid administration, produce a state of hyperaldosteronism, which also leads to hypokalemia and metabolic alkalosis (see Box 104-6).⁷⁶ In these disorders, the extracellular volume increases, and hypertension may result. In these patients, metabolic alkalosis is perpetuated by the effects of hypokalemia, rather than hypovolemia, which leads to increased ammonium production, H^+ secretion, and HCO_3^- reabsorption.

Patients with secondary hyperaldosteronism from reduced arterial blood volume, as observed in conditions like congestive heart failure and cirrhosis, do not usually develop metabolic alkalosis unless treated with diuretics. In these patients, distal sodium delivery is reduced due to the expanded reabsorption of sodium in the proximal tubule. Without high distal sodium delivery, the effect of aldosterone on sodium reabsorption and K^+ and H^+ excretion is diminished. High distal sodium delivery and elevated mineralocorticoid levels may occur together with primary mineralocorticoid secretory disorders or conditions like Liddle's syndrome, which manifest as primary hyperaldosteronism.

Alkali Administration

In normal individuals and under most circumstances, chronic administration of sodium bicarbonate will only slightly alter the systemic pH due to the relatively rapid renal excretion of excess alkali and minimal rise in plasma bicarbonate levels. Alkalosis may occur, however, if large amounts of sodium bicarbonate or any substance metabolized to bicarbonate (like the sodium salts of citrate, acetate, or lactate) are administered more rapidly, such as in the use of sodium bicarbonate to treat lactic acidosis or administration of sodium citrate in the form of massive blood transfusions. Notably, other factors contributing to alkalosis, like hypovolemia, hypokalemia, or renal impairment, will often be present.

Citrate, the anticoagulant used in blood products, is being increasingly used as an anticoagulant for CRRT. Since 1 mmol of trisodium citrate is metabolized to 3 mmol of sodium bicarbonate by the liver, metabolic alkalosis can occur from increased citrate. Metabolic alkalosis from citrate delivery in CRRT can be easily managed by decreasing the citrate infusion rate, increasing citrate and bicarbonate losses by increasing the dialysate/replacement fluid flow rate, or reducing the bicarbonate concentration in the dialysate/replacement fluid.⁷⁷

The milk-alkali syndrome results from the ingestion of large quantities of calcium carbonate, along with vitamin D, and is characterized by hypercalcemia and metabolic alkalosis. Hypercalcemia causes impaired renal function through renal vasoconstriction, renal salt wasting, and volume depletion; the latter is exacerbated by vomiting. Hypovolemia and decreased renal function are responsible for maintaining systemic alkalosis. Alkalosis also increases renal reabsorption of calcium, thereby worsening hypercalcemia.

Diagnosis of Metabolic Alkalosis

When a diagnosis of metabolic alkalosis is established, the etiology can usually be determined from the patient's history. Otherwise, alkalosis is generally due to one of three common causes: (1) emesis; (2) diuretic use; or (3) mineralocorticoid excess. Measurement of the urine chloride concentration usually helps to differentiate among these conditions. When metabolic alkalosis is associated with a reduction in ECV, Na^+ and Cl^- reabsorption are enhanced to replenish extracellular volume. In these setting, urinary Cl^- concentration should be very low, typically less than 25 mEq/L. See Table 104-3 and Figure 104-3.

TABLE 104-3 Diagnosis of Metabolic Alkalosis

| SALINE-RESPONSIVE ALKALOSIS | SALINE-UNRESPONSIVE ALKALOSIS |
|---|-----------------------------------|
| LOW URINARY $[Cl^-]$ | HIGH OR NORMAL URINARY $[Cl^-]$ |
| Normotensive | Hypertensive |
| Vomiting, nasogastric aspiration | Primary aldosteronism |
| Diuretics | Cushing's syndrome |
| Post hypercapnia | Renal artery stenosis |
| Bicarbonate therapy of organic acidosis | Renal failure plus alkali therapy |
| K^+ deficiency | Normotensive |
| Hypertensive | Mg^{++} deficiency |
| Liddle's syndrome | Severe K^+ deficiency |
| | Bartter's syndrome |
| | Gitelman's syndrome |
| | Diuretics |

Urinary Na^+ concentration is not a reliable measure of extracellular volume status in the setting of metabolic alkalosis. If all of the filtered HCO_3^- cannot be reabsorbed, then some will be excreted with Na^+ , and urinary Na^+ may be high. Thus, the volume status may incorrectly appear to be euvolemic or hypervolemic.

If the urinary Cl^- is low, indicating a hypovolemic state, then 0.9% NaCl and water administration to replenish ECV should stop aldosterone production and lead to appropriate excretion of excess HCO_3^- , improvement of hypokalemia, and correction of metabolic alkalosis. These causes of metabolic alkalosis are considered saline-responsive.

Mineralocorticoid excess, by contrast, is associated with increased extracellular volume and occasionally hypertension. Urinary Cl^- will be high, typically when higher than 40 mEq/L. Saline administration in such patients would further expand extracellular volume and worsen hypertension. Alkalosis, which in this setting is primarily due to hypokalemia, would not be corrected. These causes of metabolic alkalosis are considered saline-resistant.

The causes of saline-resistant metabolic alkalosis can be further distinguished according to whether or not hypertension is present. Hypertension tends to occur in mineralocorticoid excess states, while Bartter's and Gitelman's syndromes and exogenous alkali load are associated with normal blood pressure.

Treatment

The goals of the treatment of metabolic alkalosis are to reverse the cause of bicarbonate generation and address those factors that restrict secretion of excess bicarbonate from the kidneys. Diagnostic evaluation of metabolic alkalosis can be aided by measurement of the urine chloride concentration, systemic blood pressure, and the estimated volume status of the patient. Other clinical findings that may assist with the evaluation include vomiting, NG suctioning, or alkali or diuretic use. Reversal of the underlying cause of alkalosis may include controlling emesis, addressing the removal of gastric secretions or lowering the gastric acid content removed, and discontinuing loop or thiazide diuretics. Medications that reduce gastric acid secretion, such as proton pump inhibitors or histamine-2 receptor blockers, have been administered to improve alkalosis in patients with persistent vomiting.^{78,79} Any exogenous source of alkali, like bicarbonate, or substances that metabolize to bicarbonate (like citrate or lactate) should be discontinued as possible. Hypokalemia is common in metabolic alkalosis and should be corrected.

A reduction in renal excretion of excess bicarbonate is required to maintain metabolic alkalosis, so addressing factors that impair renal function and subsequent bicarbonate secretion will help correct

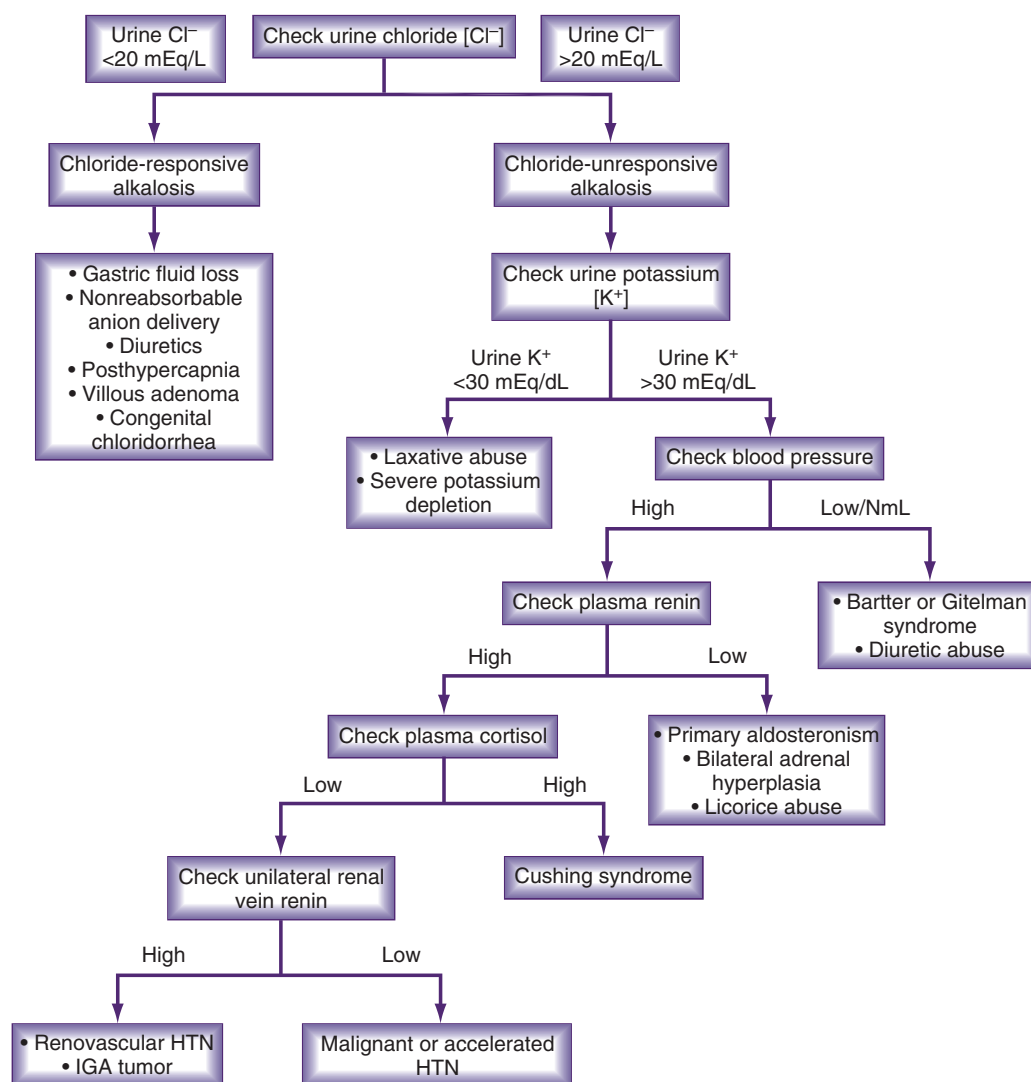

FIGURE 104-3 ■ Workup of metabolic alkalosis. (Data from DuBose TD Jr. Acid-base disorders. In: Brenner BM, editor. Brenner and Rector's the kidney. 8th ed. Philadelphia: Saunders; 2008, p. 513.)

alkalosis. Such conditions include reduced renal function, reduced arterial blood flow, K^+ depletion/hypokalemia, and Cl^- depletion/hypochloremia.

Treatment of metabolic alkalosis can be further divided on the basis of whether it responds to intravascular volume expansion. Patients with volume contraction as the cause of metabolic alkalosis are generally saline-responsive. On the other hand, patients with metabolic alkalosis due to mineralocorticoid excess, hypokalemia, or renal insufficiency are typically saline-resistant.

The treatment of metabolic alkalosis associated with volume contraction consists of volume expansion with 0.9% saline. Reexpansion of intravascular volume and correction of chloride deficiency lower proximal tubular bicarbonate reabsorption, enhance urine bicarbonate excretion, and lower the plasma bicarbonate concentration. Hypokalemia, if present, should be treated with potassium chloride. Metabolic alkalosis due to gastric acid loss, diuretics, and chloride depletion and the posthypercapnic state typically respond to 0.9% saline administration.

Saline-resistant metabolic alkalosis does not improve following administration of 0.9% saline. These patients are generally not volume depleted or chloride deficient as shown by high concentrations of

urinary chloride. In patients with excessive mineralocorticoid production, like in Conn's syndrome, use of spironolactone to inhibit mineralocorticoid activity may be beneficial. Corticosteroid therapy may need to be discontinued, and ACE inhibitors may be helpful due to their potassium-sparing effect and control of hypertension. Surgical or chemical ablation of the adrenal glands may be necessary for definitive management.

Severe hypokalemia increases tubular H^+ excretion, ammonia production, and chloride wasting. Potassium repletion corrects this defect. As potassium wasting is a central finding in mineralocorticoid excess, Bartter's syndrome, and Liddle's syndrome, potassium-sparing diuretics like amiloride or triamterene are used in these patients.

Metabolic alkalosis may be observed in patients with edematous states, including heart failure, nephrotic syndrome, and cirrhosis. This often results from the use of diuretics; however, treatment with 0.9% saline is not usually helpful in these patients. Infusion of saline in this setting will increase fluid retention and edema, and the alkalosis will not be corrected as avid Na reabsorption will reduce excretion of any excess bicarbonate. These patients are often K^+ deficient, and potassium chloride may improve the alkalosis by increasing the serum K^+ concentration. Use of potassium-sparing diuretics like amiloride and/

or aldosterone antagonists like spironolactone for these patients may be indicated.

Renal replacement therapy may be considered to correct metabolic alkalosis in situations where patients fail to respond to conventional therapies like volume expansion or K^+ repletion.⁸⁰ In such instances, dialysis with a lower bicarbonate bath concentration can quickly improve the alkalosis; however, even use of a standard bicarbonate bath concentration can be effective as the patient's serum bicarbonate level is often higher than that of the standard bath concentration. CRRT can also be used to treat metabolic alkalosis, but attention to the CRRT fluid buffer composition is warranted since bases such as bicarbonate, citrate, or lactate may increase the serum bicarbonate concentration at high effluent/ultrafiltration rates.⁸¹

Hydrochloric acid (HCl) for the treatment of metabolic alkalosis is usually reserved for patients with severe symptoms who do not respond to conventional therapy with intravenous fluids and for correction of electrolyte derangement. The arterial pH is usually higher than 7.55, and there may be evidence of seizures, altered sensorium, or cardiovascular complications. Dilute HCl (0.1 N) should be given through a central intravenous catheter, and careful vigilance of catheter integrity and surrounding tissue should be maintained to avoid complications of acid extravasation, which may cause tissue necrosis.^{82,83} Hemolysis can also complicate therapy with HCl. Titration of HCl can be challenging, and the goal of therapy is to lower the arterial pH to approximately 7.5, rather than to normalize the value.

DIAGNOSIS OF ACID-BASE DISORDERS

A systematic approach is necessary for determining which acid-base disorder or disorders are present.⁸⁴ Accurate interpretation of acid-base balance requires simultaneous measurements of arterial pH and plasma electrolytes. The arterial blood gas (ABG) test directly measures arterial pH and P_{aCO_2} . The bicarbonate concentration from the ABG test is calculated using the Henderson-Hasselbalch equation, while the bicarbonate concentration on venous chemistry panel is measured directly as "total CO_2 " with an ion-selective electrode. The calculated value for HCO_3^- reported with the ABG test should be within 2 or 3 mEq/L of the measured HCO_3^- concentration obtained on the electrolyte panel. A discrepancy in the values suggests either the samples were not obtained simultaneously or that a laboratory error has occurred. The cause of acid-base disturbances is determined by examining the pH, P_{aCO_2} , and plasma electrolytes (primarily plasma bicarbonate) in the context of a given clinical situation. Analysis involves identification of the likely dominant acid-base disorder, followed by an assessment of the compensatory response. A stepwise approach to the diagnosis of acid-base disorders follows and is summarized in Box 104-7.^{5,6}

The initial screening for an acid-base disorder entails obtaining a detailed history and performing a physical examination. The history and physical examination usually strongly suggest the acid-base disorder that is present. A history of diuretics or vomiting suggests metabolic alkalosis. A history of diarrhea, alcoholism, or diabetes suggests metabolic acidosis. Stigmata of liver disease on the physical examination may signify the presence of respiratory alkalosis, while findings of volume contraction suggest metabolic alkalosis. Kussmaul respiration is often associated with DKA and severe metabolic acidosis. Medications that can affect acid-base balance (e.g., laxatives, diuretics, topiramate, or metformin) should be considered as well as signs of intoxication that may be associated with acid-base disturbances.

The first step in acid-base analysis is to determine if the patient has acidemia or alkalemia by examining the arterial pH. If acidemia is present then an acidosis must be present; similarly, if alkalemia is present, then alkalosis must be present. The second step is to determine whether the deviation in the pH (acidemia or alkalemia) is due to a primary respiratory or metabolic derangement by examining the P_{aCO_2} and plasma bicarbonate concentration. In acidemia, a low plasma bicarbonate concentration denotes primary metabolic acidosis, while an elevated P_{aCO_2} points to primary respiratory acidosis. Likewise, in

BOX 104-7

Stepwise Approach to Diagnosing Acid-Base Disorders

INITIAL SCREENING

Consider the clinical setting by obtaining history and physical examination. Obtain arterial blood gases (ABG) and electrolytes simultaneously. Compare bicarbonate on ABG to venous electrolytes to ensure the calculated bicarbonate on ABG is within 2-3 mEq/L of measured bicarbonate on electrolyte panel.

STEPS

1. Examine pH to determine if the patient has acidemia or alkalemia.
2. Look at PCO_2 , HCO_3^- to determine if the primary process is metabolic or respiratory.

3. If a primary respiratory disorder is present in step 2, determine if it is acute or chronic.
4. Calculate the serum anion gap.
 - a. Anion gap = $Na^+ - (Cl^- + HCO_3^-)$
5. If a metabolic disturbance is present from step 2 or high anion gap from step 4, determine if the respiratory system is adequately compensating.
 - a. Expected P_{aCO_2} in acidosis: $P_{aCO_2} = (1.5 \times HCO_3^-) + 8 \pm 2$
 - b. Expected P_{aCO_2} in alkalosis: $P_{aCO_2} = 40 + 0.7 \times (HCO_3^-_{meas} - HCO_3^-_{normal}) \pm 5$
6. If anion gap is elevated, then calculate the Delta Delta Ratio (Δ/Δ) to assess for other simultaneous disorders.
 - a. Δ/Δ compares the change in the anion gap to the change in bicarbonate.
 - b. If ratio is between 1 and 2, then pure elevated anion gap acidosis is present.
 - c. If <1 , then there is a simultaneous normal anion gap acidosis is present.
 - d. If >2 , then there is a simultaneous metabolic alkalosis present or a compensated chronic respiratory acidosis.

alkalemia, an elevated plasma bicarbonate concentration signifies primary metabolic alkalosis, whereas a low P_{aCO_2} is consistent with primary respiratory alkalosis. If a primary respiratory disturbance is present from step 2, the third step is to assess if it is acute or chronic by comparing pH and P_{aCO_2} by the formulas in Table 104-1.⁶ If no primary respiratory disturbance is present, step 3 is skipped.

The fourth step is to calculate the serum AG. If primary metabolic acidosis is present from step 2, the serum AG is used to diagnose high-AG metabolic acidosis. The AG should be adjusted for hypoalbuminemia. Even if metabolic acidosis is not present or the pH and P_{aCO_2} are within normal range, the serum AG should always be calculated since a mixed disorder can exist with a normal pH, P_{aCO_2} , and plasma bicarbonate concentration, which is seen with high-AG metabolic acidosis and concurrent metabolic alkalosis. If a high AG is present, ancillary tests to consider for differentiating the causes include plasma and urine ketones for ketoacidosis, plasma creatinine for renal failure, plasma L-lactate for lactic acidosis, plasma osmolality to calculate an osmolal gap and assess for toxic alcohol ingestions, and urine microscopy for crystals if ethylene glycol is suspected. If the primary metabolic acidosis is non-AG metabolic acidosis (plasma bicarbonate concentration is low without elevated AG), the UAG can help differentiate GI from renal causes.^{85,86}

If a metabolic disturbance is present from step 2 or 4, the fifth step is to determine if the respiratory system is adequately compensating. In metabolic acidosis, Winters' formula should be used to calculate the

expected Paco_2 for the degree of acidosis present. If the measured Paco_2 is higher than the calculated expected Paco_2 , then concomitant respiratory acidosis is present. If the measured Paco_2 is lower than the expected Paco_2 , then respiratory alkalosis is also present. In metabolic alkalosis, the normal respiratory response is less predictable. However, in general, the Paco_2 should be between 40 and 50 mm Hg for appropriate compensation for metabolic alkalosis.⁶

If high-AG metabolic acidosis is present from step 4, the last step is to determine the existence of any concurrent metabolic disturbances (such as non-AG metabolic acidosis or metabolic alkalosis) by comparing the degree of change in the serum AG with the change in the plasma bicarbonate level. This is done to assess the extent of contribution of the AG-producing process to the actual acidosis. This measurement is called Delta Delta Ratio⁸⁴:

$$\text{Delta Delta Ratio} = \Delta\text{AG} / \Delta\text{HCO}_3^- = (\text{AG} - 12) / (24 - \text{HCO}_3^-)$$

If the metabolic disturbance is solely due to an elevated AG, the HCO_3^- should decrease by the same amount that the AG increases. A Delta Delta Ratio between 1 and 2 usually indicates uncomplicated

high-AG metabolic acidosis. A Delta Delta Ratio higher than 2 usually indicates a lesser fall in HCO_3^- than would be expected given the change in the AG and the presence of concurrent metabolic alkalosis. An example of combined AG metabolic acidosis and metabolic alkalosis is volume contraction from vomiting in the setting of DKA. A Delta Delta Ratio less than 1 indicates a greater fall in HCO_3^- levels than would be expected given the increase in the AG and therefore the presence of simultaneous non-AG metabolic acidosis. This might occur when lactic acidosis is superimposed on severe diarrhea. In this situation, the additional fall in HCO_3^- levels is due to further buffering of an acid that does not contribute to the AG.⁸⁴

SUMMARY

Acid-base disorders are common in the ICU and need to be anticipated in all critically ill patients. A clinician must be able to accurately monitor the acid-base status in order to promptly recognize derangements and implement appropriate interventions to prevent life-threatening complications as a result of the disturbance.

KEY POINTS

1. Metabolic and mixed acid-base disorders are common in ICU patients and require early detection with a search for the underlying cause and initiation of appropriate treatment to prevent potentially fatal complications.
2. Metabolic acidosis can be categorized as high or normal anion gap (AG) acidosis. High AG acidosis is frequently due to lactic acidosis, ketoacidosis, toxic ingestions, or renal failure; non-AG acidosis is mostly due to gastrointestinal (GI) or renal bicarbonate loss. Diagnostic tests for differentiating causes of high AG acidosis include plasma and urine ketones, plasma creatinine, plasma L-lactate, plasma osmolality and osmolal gap, and urine microscopy for crystals. The urine AG can help differentiate causes of non-AG acidosis.
3. The serum AG should always be calculated in the ICU since the presence of a significantly elevated serum AG represents metabolic acidosis, irrespective of pH or plasma bicarbonate. The serum AG must be adjusted for hypoalbuminemia.
4. Compensation for primary metabolic acidosis is determined by Winters' formula. The delta-delta gap is calculated to identify a concomitant metabolic disorder.
5. Treatment for metabolic acidosis involves treating the underlying cause. Alkali therapy is often given for non-AG acidosis but is rarely indicated in high AG metabolic acidosis unless the arterial pH is less than 7.15 or for salicylate intoxication.
6. Metabolic alkalosis may be initiated by acid loss or bicarbonate gain and maintained by renal mechanisms associated with bicarbonate resorption, including extracellular fluid volume contraction, chloride depletion, hypokalemia, and elevated mineralocorticoid activity.
7. Metabolic alkalosis is most often caused by volume depletion with upper GI loss of hydrogen chloride (recurrent vomiting or nasogastric suction) or by diuretic use with renal loss of H^+ .
8. The evaluation of metabolic alkalosis begins with measurement of the urine chloride and estimation of the extracellular volume status. Metabolic alkalosis involving the loss or excess secretion of chloride is termed *chloride-responsive*.
9. Compensation for primary metabolic alkalosis is estimated by increase in $\text{Paco}_2 = 0.75 \times \Delta \text{HCO}_3^-$.
10. Treatment for metabolic alkalosis involves treating the underlying cause by administering intravenous 0.9% saline in chloride-responsive metabolic alkalosis and correcting mineralocorticoid excess and primary hyperaldosteronism in patients with a chloride-resistant metabolic alkalosis.

- The problem of NRTI-induced lactic acid acidosis in patients with HIV is evaluated by a case-controlled study to determine risk factors. Two factors were identified to be associated with an increased risk of lactic acidosis: (1) creatinine clearance less than 70 mL/min and (2) a low CD4⁺ T-lymphocyte count before inception of therapy. Interestingly, the total cumulative exposure to NRTIs was not associated with an increased risk of lactic acidosis. Therefore, creatinine clearance and CD4⁺ T-lymphocyte count should be monitored in patients infected with HIV and could lead to modifications in antiretroviral therapy to diminish the risk of occurrence of lactic acidosis.

This paper identifies an important and recently realized cause of high-AG acidosis in the critical care setting. This is an unsuspecting yet very common setting in which metabolic acidosis due to accumulation of this compound may develop; hence, this information is critical to the clinician when formulating diagnostic and therapeutic plans for high-AG acidosis.

■ References for this chapter can be found at expertconsult.com.

This paper by the same senior author who performed the first controlled clinical trial of dichloroacetate for treatment of lactic acidosis in adults demonstrates that the maximum lactate-lowering effect of dichloroacetate is dose dependent but independent of time after administration. The study suggests that dichloroacetate could be effective in reducing lactate levels in patients with mild hyperlactatemia. This may be an important observation for ongoing investigation in low-level hyperlactatemia as it applies to a number of clinical circumstances.

Water is the body's most abundant component. Without ingesting sufficient fresh water, humans can survive for just a few days. Ingested water, plus water produced endogenously, must be appropriately excreted to maintain homeostasis. In the human body, water has many functions: intracellular, intravascular, and extracellular carrier of essential substances; body coolant; lubricant; reactant and product in metabolic reactions; and shock absorber (e.g., CSF surrounding the brain). In critically ill patients, water metabolism and balance present special challenges. Patients are admitted to the intensive care unit (ICU) because of disordered water homeostasis, while it is disturbed by ICU treatments.

Water accounts for 50%-67% of an average person's weight. Because fat has a lower percentage of water and women tend to have more fat, their proportion of water is lower (52%-55%) than that of men (60%). Water percentage is lower in the elderly and obese. A 70-kg man has ~40 L of water: ~25 to 27 L intracellularly, ~7 L extracellularly, and ~4 L intravascularly. Liquid water is the body's most common molecule, although some water is found in hydrated compounds. Hypovolemia and hypervolemia significantly threaten life. Therefore, the body defends fluid volume and osmolarity within very narrow ranges.

■ WATER INGESTION AND PRODUCTION

Water is ingested via the gastrointestinal tract or infused via venous (or interosseous) routes. Water intake is regulated by thirst, although normally humans sufficiently self-regulate their intake so that thirst is only occasionally activated. Thirst is also activated by salty food, hot weather, and exercise. The latter two cause sweating and increased respiratory water loss. Adequate water intake is ~3 L/day for men and ~2.2 L/day for women.

Thirst: Thirst is vital for defending against hypovolemia. Hypovolemic thirst is triggered when body water levels decrease to ~2% to 3%. Hypertonic thirst occurs when osmolality increases to >290 mOsm/kg. Hypotension and hemorrhage also stimulate thirst. Peripheral and central mechanisms detect and react to these physiologic perturbations, leading organisms to seek and ingest appropriate fluids and fluid volumes. Drinking stimulates oral and pharyngeal receptors, thereby providing hypothalamic input to end the thirst sensation. Thirst ends even before plasma tonicity is reduced, likely preventing water over-ingestion. Thirst sensation is so powerful that normal subjects do not become hypernatremic if they have access to water. The inability to find, detect, react, request, or drink water adequately can cause severe illness and even death. The inability to self-regulate water intake—for example, during anesthesia and critical illness—makes patients totally dependent on caregivers to prevent and treat water disorders.

In the elderly, decreased kidney function, physical and cognitive problems, blunted thirst, and polypharmacy increase dehydration risk. There is also reduced renal sodium conservation (altered renal tubular function, greater atrial natriuretic peptide (ANP) secretion, lower renin-angiotensin-aldosterone secretion), decreased renal water excretion (lower renal blood flow, glomerular filtration rate, and distal renal tubular diluting capacity; greater renal passive water reabsorption and ADH secretion), and reduced solute delivery caused by poor nutrition, limiting free water excretion. A water-loss dehydration prevalence of up to 30% is observed in the elderly with concomitant morbidity.¹ A positron emission tomography study revealed

age-associated changes in central nervous system (CNS) satiation patterns in response to hyperosmolarity, which were associated with inadequate hydration.² Paradoxically, elderly patients with worsening heart failure have increased thirst.³

Metabolic Water Production: Water is the principal end product of nutrient oxidation (Table 105-1). Although more water molecules are produced per mole of fat than per mole of glucose (129 vs. 36) per kilocalorie, overall, aerobically oxidized carbohydrates contribute to ~15% more water molecules than lipids.⁴ An increased metabolic rate increases metabolic water production.

Water Loss

Water is lost through many routes but mainly through the kidneys. Urine volume and composition depend on hydration status and the osmole load. Fecal losses are generally small, while sweating can cause large losses.

Renal Function: Renal function, the major mechanism defending against disordered water balance, protects blood osmolarity within a narrow range by altering urine osmolarity over a wide range (50-1200 mOsm). Concentrated urine is formed by creating an osmotic gradient that progressively increases from the corticomedullary border to the tip of the inner medulla.⁵ When the body must rid itself of excess water, urine can be diluted to as low as 50 mOsm.

Aging reduces the maximum urine-concentrating ability. Compared with younger individuals, those aged 60 to 79 years had an ~20% reduction in maximum urine osmolality, an ~50% decrease in the ability to conserve solute, and a 100% increase in minimum urine flow rate.⁶

Insensible Losses: Insensible losses include transepidermal diffusion and evaporation of solute-free water plus evaporative water loss from the respiratory tract. Total insensible losses, ~800 mL/day in unstressed adults, are equally divided between skin and respiratory tract losses. Activity increases respiratory water losses so that active adults can lose up to 50 mL/h. Age reduces transepidermal water losses.⁷ In febrile patients, insensible losses can increase by four- to six-fold.⁸

Respiratory water losses are affected by many factors (see Table 105-1). In normal subjects, mouth breathing resulted in 42% greater water loss compared with nose breathing.⁹ Cold exposure increases the need to humidify and warm inspired gases, thus increasing water losses. Using heat-and-moisture-retaining face masks during sleep reduced these losses.¹⁰ In critically ill patients, rapid spontaneous respiratory rates increase respiratory water losses, while endotracheal tubes bypass the natural warming and humidifying mechanisms, requiring inspiratory gases to be artificially humidified and warmed.

Sweating: Sweating is mainly a mechanism of thermoregulation, although it also occurs in response to psychologic stress (see Table 105-1). Sweating involves the secretion of water-rich liquid by the eccrine glands located throughout the body surface and secretion of protein-, lipid-, and steroid-containing sweat by the apocrine glands found in the axilla, mammary, perineal, and genital areas. Thermoregulatory sweating mainly involves eccrine secretion occurring in response to intrinsic (fever, exercise) and extrinsic stimuli (elevated environmental temperatures). Maximum adult sweat rates can be 2 to 4 L/h during intense exercise.

TABLE 105-1 Water and the Human Body**WATER BALANCE**

Water balance = (water intake + metabolic water production) – water loss
 ~5%-10% of body water turns over daily
 Total body water (estimate): Children = $0.6 \times (\text{wt, kg})$
 Adult men = $0.6 \times (\text{wt, kg})$
 Adult women = $0.5 \times (\text{wt, kg})$

RECOMMENDED WATER INTAKE

Average energy expenditure (EE) and environmental exposure = 1.0 mL/kcal EE⁴⁰
 Increased activity, sweating, and solute load = 1.5 mL/kcal EE⁴⁰

METABOLIC WATER

Water produced by metabolism (usually oxidation) of endogenous substrates
 Approximately 250-350 mL water/day (3-4 mL/kg/day)
 Example: Glucose oxidation:

Metabolism produces ~110 g water/100 g fat, 41 g water/100 g protein and 55 g water/100 g starch
 ~3 g water released per gram metabolized glycogen

WATER LOSS

Respiratory water loss (250-350 mL water/day) is influenced by temperature and humidity of inspired air.
 Urinary loss depends on water and solute intake
 Insensible losses—skin and respiratory system = 0.7 L/day
 Fecal loss—0.1 L/day
 Sweating—0.1 L/day
 Disease-associated losses—e.g., nasogastric drainage, vomiting, diarrhea

WATER AND HEAT LOSS

Heat exchange = radiation \pm conduction \pm convection (+evaporation)
Heat gain via radiation, conduction, and convection plus endogenous body heat production
Heat loss via radiation, conduction, convection, and evaporation
 Sweat evaporation
 Heat of water vaporization = 580 calories/m at normal skin temperature
 580 calories/g = heat loss to cool down 580 g of water 1°C
 Evaporation rate influenced by
 Water temperature at air-water interface
 Air temperature
 Humidity of surrounding air—higher humidity lowers evaporation rate
 Area of air-water interface
 Water's chemical composition—vaporization rate decreases as salt content increases
 Wind speed
 Sweat that drips or is wiped off does not contribute to cooling
 Burn patients lose much water and heat through evaporation from open wounds. Therefore, they should be treated in warm humid environments and burned areas covered.

Regulation of Water Balance

Regulating water balance involves central and peripheral volume and osmolarity sensors, providing neural input to the brain and other organs, thereby activating a cascade of endocrine and local activity.

Antidiuretic Hormone (ADH)/Arginine Vasopressin (AVP): ADH is a peptide, produced by the neurons of the hypothalamic paraventricular and supraoptic nuclei as a prohormone comprising vasopressin, neurophysin II, and copeptin. Neurons containing osmoreceptors have excitatory synapses with prohormone neurosecretory cells. ADH, bound to the carrier protein neurophysin II, then travels down the pituitary stalk (infundibulum) axons to the posterior pituitary where it is stored and secreted into the circulation.

ADH production and secretion are also stimulated by angiotensin II and decreased blood volume detected by atrial stretch-sensitive low-pressure/vascular volume baroreceptors. A 5% to 10% blood volume decrease is necessary for substantial ADH release. ADH is also secreted when carotid sinus and aortic arch baroreceptors detect a 10% blood pressure drop. Copeptin, the C-terminal fragment of the

prohormone, is more stable than ADH. Copeptin plasma concentrations are often used as an ADH surrogate.

ADH levels increases the water permeability of distal renal tubules and collecting ducts, thus increasing water reabsorption and resulting in greater urine osmolarity and reduced renal water excretion. ADH binds to vasopressin-2 receptors on renal epithelial cells. These G protein-coupled receptors activate adenylyl cyclase, converting ATP to cyclic AMP (cAMP). Increased cAMP increases the transcription of the aquaporin-2 gene, increasing aquaporin-2 in collecting duct cells and triggering the fusion of aquaporin-2 water channels to the apical membranes of distal tubule and collecting duct epithelial cells, allowing water to move down an osmotic gradient into the nephron. Aquaporin-3, located on the opposite side of the nephron, permits water leaving the nephron to be reabsorbed into the blood. ADH also upregulates aquaporin-3.

cAMP also activates protein kinase A, leading to protein phosphorylation (aquaporin-2 and thiazide-sensitive sodium chloride cotransporter) and upregulating expression of urea transporters, thereby increasing urea permeability of the collecting duct. There is also greater sodium absorption across the ascending loop of Henle. These two effects further increase distal tubular and collecting duct water reabsorption.

Renin-Angiotensin-Aldosterone System (RAAS): RAAS is a hormonal system stimulated by changes in renal blood flow. When renal blood flow or blood pressure decrease, juxtaglomerular cells in the renal afferent arterioles activate prorenin, which is cleaved to renin. The latter is secreted into the circulation where it converts angiotensinogen, an α -2-globulin synthesized by the liver, to angiotensin I. Angiotensinogen production is enhanced by estrogen, thyroxine, and glucocorticoids. There is evidence that cytokines (e.g., interferon- γ) also induce angiotensin production, a possible mechanism for maintaining blood pressure during sepsis.¹¹

Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme (ACE). ACE, a glycoprotein found mainly in the lungs and also in endothelial cells and plasma, also breaks down the potent vasodilator bradykinin, providing another mechanism for increasing blood pressure. Angiotensin II, a potent vasoconstrictor, increases blood pressure and decreases renal medullary blood flow and glomerular filtration, while vasoconstricting afferent and efferent arterioles. These changes increase sodium and water reabsorption in the loop of Henle. Hydrogen ion is excreted coupled with bicarbonate reabsorption. Angiotensin II's effects are attributable to its enhancing proximal and distal sodium/hydrogen ion exchanger, basolateral membrane sodium/bicarbonate ion cotransporter, sodium/potassium ion ATPase activity, and distal tubular epithelial sodium channel. Angiotensin II also stimulates posterior pituitary ADH release, further causing water retention.

Angiotensin II's major actions occur via the stimulation of AT-1 receptors located in the kidney, brain, heart, blood vessels, and adrenal cortex. The activated receptor couples to G proteins, activating phospholipase C and generating diacylglycerol and inositol trisphosphate. The latter increases cytosolic Ca^{2+} concentrations, which then activate intracellular kinases such as protein kinase C and tyrosine kinases. The activated AT-1 receptor also inhibits adenylyl cyclase. Angiotensin II also stimulates lower affinity AT-2 receptors, leading to effects opposite those caused by AT-1 receptor stimulation. AT-2 receptors lower blood pressure by increasing nitric oxide production, enhancing sodium excretion, and inhibiting renin production.¹² The latter action is a feedback loop designed to limit further angiotensin II production.

Angiotensin II stimulates adrenal cortical aldosterone synthase, which synthesizes aldosterone from deoxycorticosterone. Aldosterone regulates blood pressure by binding to the mineralocorticoid receptors of the renal distal tubular and collecting duct epithelial cells, thereby increasing expression and activity of ion channels in the distal nephron. By upregulating and activating the basolateral Na-K-ATPase pumps, aldosterone increases renal tubular sodium and water reabsorption plus the excretion of hydrogen ions and potassium, increasing body fluid volume and blood pressure.

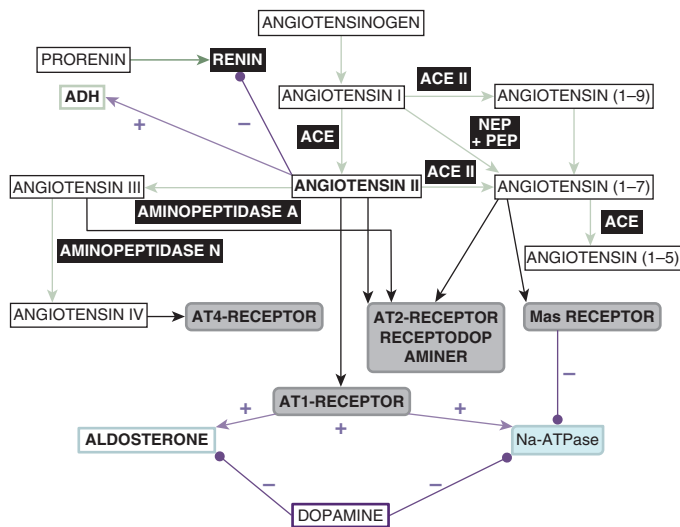

FIGURE 105-1 ■ RAAS system plus its interactions with ADH and dopamine. ADH, antidiuretic hormone; ACE, angiotensin converting enzyme.

The endocrine RAAS system is augmented by an RAAS with intrarenal paracrine, autocrine, and intracrine activity. Angiotensinogen produced intrarenally is converted by local renin to angiotensin I, which is then metabolized by ACE to angiotensin II and by ACE2 to angiotensin I-VII.¹³ Although most local effects are attributed to angiotensin II operating through AT-1 receptors, angiotensin I-VII operating through Mas receptors counteracts many of the effects of angiotensin II/AT-1, leading to diuresis, natriuresis, and renal vasodilation (Fig. 105-1). Other local mediators include angiotensin III (angiotensin II-VIII) working via the AT-1 receptors and angiotensin IV through the AT-4 receptors.¹⁴ Intrarenal angiotensin IV increases cortical blood flow and decreases sodium transport. In addition to the extracellular processing of these mediators, there is evidence that angiotensin II and angiotensin I-7 also exist intracellularly.¹⁵

Natriuretic Factors (Peptides): Natriuretic factors consist of a peptide family involved in water and sodium homeostasis that counteract RAAS effects. ANP, released by atrial myocytes in response to atrial distention secondary to elevated blood volume,¹⁶ is also secreted in response to sympathetic stimulation (α - and β -stimulation), angiotensin II, and endothelin. Cardiac ventricles, brain, adrenal glands, and kidneys (where it also acts as an autocrine/paracrine factor) are additional synthesis sites. ANP decreases circulating water and sodium, reducing atrial distention, and ultimately, lowering blood pressure. Another family member is brain natriuretic peptide (BNP), a peptide so named because it was first identified in porcine brain, although in humans it is mainly released by the heart in response to excessive cardiomyocyte distention. Biologically inactive circulating N-terminal fragments of ANP and BNP prohormones are used as biomarkers.

ANP and BNP increase glomerular filtration rates, reduce sodium and water reabsorption, inhibit renin release, and in proximal tubules, inhibit angiotensin II activity. The natriuretic peptides bind to NPR-A and NPR-B receptors, which are membrane guanylate cyclases that are characterized by a single protein containing both receptor and enzyme that produce cyclic GMP.¹⁷ cGMP targets cGMP-dependent protein kinases, cGMP-gated ion channels, and cGMP-regulated cyclic nucleotide phosphodiesterases. Changes in these enzymes and channels cause vasorelaxation, inhibit medullary collecting duct sodium reabsorption, and increase glomerular filtration rate by dilating afferent and constricting efferent arterioles, leading to greater glomerular capillary hydraulic pressure that enhances ultrafiltration. ANP, more effectively than BNP, stimulates cGMP production. ANP-induced diuresis and natriuresis occur, in part, by V2 receptor-mediated action of ADH in

the collecting ducts. Natriuretic peptide-induced increase in water and sodium excretion protects the body from overhydration. In pathologic conditions, such as congestive heart failure, ANP and BNP are stimulated by atrial overload secondary to the heart's inability to adequately empty.

Dopamine: The importance of dopamine in water homeostasis remains unclear, although renal production is increased by volume expansion, leading to natriuresis and water loss. Dopamine, synthesized in the renal proximal tubule from circulating L-dopa by L-amino acid decarboxylase, increases the glomerular filtration rate and diminishes sodium reabsorption in proximal tubules and collecting ducts. Dopamine, via D1 receptors, stimulates c-AMP generation and via D1/D5 receptor heteromers, stimulates phospholipase C, inhibiting both the Na-K-ATPase pump and sodium/hydrogen ion exchanger-3. D2-like receptors (D2, D3, and D4) also inhibit Na⁺-H⁺ exchanger 3, although the effects of D1 receptors are more dominant. Caveolin-1, a membrane scaffolding protein, helps organize the D1 receptor signaling pathway and intracellular effects.¹⁸ Dopamine also decreases aldosterone secretion¹⁹ and inhibits the antinatriuretic effects of angiotensin II.²⁰ Dopamine is metabolized by the enzymes catechol-O-methyltransferase and monoamine oxidase. Some of the effects of ANP are likely mediated by dopaminergic mechanisms.²⁰

Local renal prostaglandin (PGE-1 and PGE-2) generation is associated with increased basolateral membrane Na-K-ATPase.²¹ The renal nitric oxide/endothelin system appears to be active in collecting ducts. Endothelin-1, operating via the autocrine and paracrine mechanisms, is a diuretic/natriuretic factor inhibiting ADH-mediated osmotic water permeability.

Evaluating Water Balance

There are various ways to evaluate water balance (Table 105-2). In the ICU, water balance is generally assessed using body weight and fluid input-output. However, both methods have limitations.

WATER METABOLISM DISORDERS

Abnormal (hypervolemic or hypovolemic) water balance attributable to various intrinsic and extrinsic etiologies result in ICU admissions when the physiologic derangement endangers survival and/or requires treatment under close monitoring.

Hypervolemic Disorders

Hypervolemic disorders are caused by excessive water ingestion and/or the inability to excrete excess body water.

Water Intoxication: The classic example of abnormal positive water balance is water intoxication (water poisoning or hyperhydration), where an individual consumes very large volumes of water. Such excess water intake overwhelms the kidney's capacity to excrete water (maximum daily renal capacity ~15 L), despite maximal dilution (urine osmolality of ~50 mOsm/L).^{22,23} This situation results in hyponatremia, hypochloridemia, and hypokalemia. Brain edema occurs secondary to the extracellular to intracellular concentration gradient, leading to headache, delirium, seizures, coma, and death. Other symptoms include nausea, vomiting, twitching, and muscle weakness.

Water intoxication (psychogenic polydipsia) is largely observed in psychiatric patients (predominantly in schizophrenia but also in anorexia nervosa). It is hypothesized that schizophrenics who develop water intoxication have impaired hippocampal regulation, resulting in increased ADH secretion in response to psychologic stimuli. Another cause might be the drugs used to treat schizophrenia.²⁴ Forced water intake in children can also lead to water intoxication, as can excessive drinking in marathon runners and military trainees. Excessive water drinking among users of the recreational drug ecstasy (3,4-methylenedioxymethamphetamine) can cause water intoxication.²⁵

TABLE 105-2 Evaluating Water Balance**QUANTIFYING INPUT AND OUTPUT**

Clinical computation

Fluid balance = input (all intravenous and enteral intakes) – output (urine, gi, other drainages)

Often does not include

Intake: Accurate quantification of blood products, irrigation fluids

Output: Diarrhea, fluid lost into linens and bandages, insensible losses (skin, respiratory), sensible losses (sweating due to fever, surface exudation from burns)

BODY WEIGHTFluid balance = Δ body weight

Requires accurate scale and bed tearing

Tare weight = weight of bed without patient but with sheets, pillows, etc.

Net weight (patient weight) = gross weight (total weight) – tare weight

URINE SPECIFIC GRAVITY U_{sg} = density of urine/density of water

Range: 1.003–1.035

Euhydration: 1.010–1.026

High-molecular-weight substances, e.g., glucose, protein, and radiographic contrast, can increase $U_{sg} > 1.035$.**SERUM AND PLASMA OSMOLALITY/OSMOLARITY**

Osmolality = osmoles of solute/liter solution

Osmolality = osmoles of solute/kilogram solvent

Urine and plasma osmolalities should be measured but can be estimated

Calculated serum osmolality (when using SI units [mmol/L])

Calculated serum osmolality = $2(\text{Na}^+) + 2(\text{K}^+) + \text{glucose} + \text{urea}$

OR

Calculated serum osmolality = $2(\text{Na}^+) + \text{glucose} + \text{urea}$ Calculated serum osmolality (when Na^+ is mEq/L and glucose and BUN are [mg/dL])Calculated serum osmolality = $2[\text{Na}^+] + [\text{glucose}]/18 + [\text{BUN}]/2$ Normal serum osmolality: 275–290 mOsm/kg. 295–300 mOsm/kg indicates impending dehydration; >300 mOsm/kg indicates dehydration.

Urine: specific gravity vs. osmolality

Unlike specific gravity, osmolality is unaffected by the number and size of particles in solution. Urine containing glucose and/or protein will have a specific gravity $>$ osmolality. $U_{sg} = 1.020$ – 1.030 corresponds to osmolality of 800–1200 mOsm/kg H_2O $U_{sg} = 1.005$ is an osmolality <100 mOsm/kg H_2O

Normal kidneys can concentrate urine to an osmolality 4 times greater than serum and dilute urine to 25% of serum osmolality.

ELECTROLYTE-FREE WATER CLEARANCEElectrolyte-free water clearance ($T^e_{\text{H}_2\text{O}}$) – amount of water in urine free of solutes $T^e_{\text{H}_2\text{O}} = V [(U_{\text{Na}} + U_{\text{K}})/P_{\text{Na}}] - 1$ V = total urine volume U_{Na} = urine (Na^+) U_{K} = urine (K^+) P_{Na} = plasma (Na^+)Positive $T^e_{\text{H}_2\text{O}}$ – water is being excreted (e.g., causing hypernatremia)Negative $T^e_{\text{H}_2\text{O}}$ – water is being reabsorbed (e.g., causing hyponatremia)**FREE WATER DEFICIT**

In hypernatremia, estimated free water deficit

Water deficit = $\text{TBW} * \{(\text{serum } [\text{Na}]/140) - 1\}$ TBW = estimated total body water: men – $0.6 * \text{Wt}$ (kg); women – $0.5 * \text{Wt}$ (kg). In the elderly and those significantly dehydrated: men – $0.5 * \text{Wt}$ (kg); women – $0.4 * \text{Wt}$ (kg)

This estimate does not account for ongoing water (i.e., insensible, urine, gastrointestinal tract) or iso-osmotic fluid (i.e., osmotic diuresis, diarrhea) losses that continue to contribute to water deficit.

BIOELECTRIC IMPEDANCE

Noninvasive method used to estimate total body water based on the assumption that only body water conducts electricity while fat, which has little water content, restricts the flow of current.

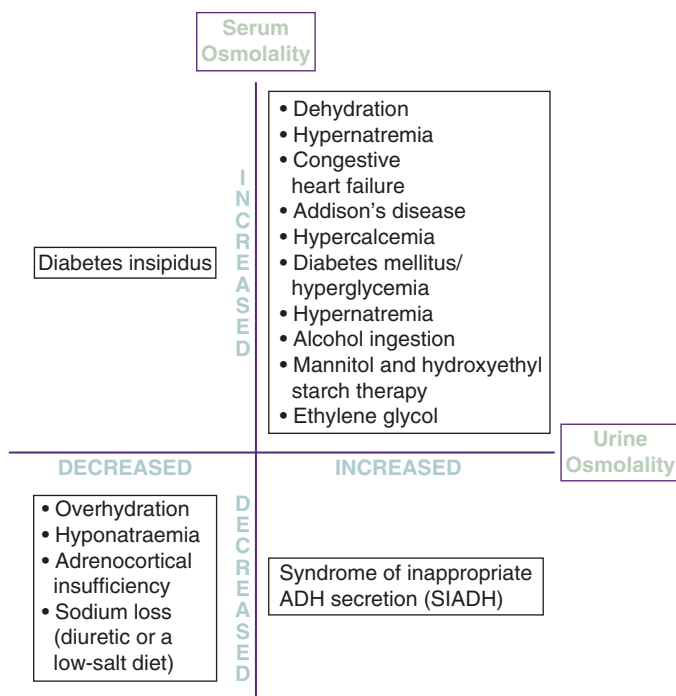

Iatrogenic causes of water intoxication include excessive, rapid water ingestion before pelvic ultrasound examinations and transurethral resection of the prostate syndrome. The latter occurs when a large volume of nonconducting (electricity) water plus glycine irrigation solution is absorbed through the prostatic veins and sinuses. The amino acid glycine is rapidly metabolized, causing water overload, hyposmolality, and hyponatremia. The introduction of bipolar cautery, which does not disperse electric current, permits using electrolyte-containing irrigation solutions (e.g., normal saline), thereby preventing hyposmolality and hyponatremia but not fluid overload. The absorption of water–glycine distention medium during operative hysteroscopy can also lead to intravascular volume overload and water intoxication.

Treatment of water intoxication involves water restriction and loop diuretics. Hypertonic saline is rarely required and should only be considered in cases of severe hyponatremia. Too rapid a correction of hyponatremia can result in central pontine myelinosis.

Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH): SIADH causes hyponatremia and hyposmolality because of impaired water excretion secondary to inappropriate, continued secretion, or action of ADH despite normal or increased plasma volume. ADH promotes water reabsorption without affecting sodium reabsorption, leading to dilutional hyponatremia because of water excess rather than sodium deficiency.

Excessive water reabsorption activates volume receptors causing the secretion of natriuretic peptides and natriuresis. Eventually, a steady state is reached with urinary sodium excretion matching sodium intake. Therefore, only when water intake exceeds the reduced urine output does hyponatremia develop. Importantly, hyponatremia does not occur with severely restricted water intake. In addition to inappropriate ADH secretion, SIADH may include inappropriate thirst sensation, leading to water intake in excess of free water excretion. This increased water intake helps maintain hyponatremia.

SIADH includes hyponatremia, inappropriately elevated urine osmolality (>100 mOsm/kg), and reduced serum osmolality in a euvolemic patient (Fig. 105-2). SIADH should be considered when these findings occur in the setting of otherwise normal cardiac, renal,

**FIGURE 105-2** ■ Relationships between plasma and urine osmolality.

adrenal, hepatic, and thyroid function; absence of diuretic therapy; and absence of other factors that stimulate ADH secretion such as hypotension, severe pain, nausea and stress.

Impaired ADH regulation in SIADH:

- Type A—erratic, unregulated ADH release unrelated to plasma osmolality
- Type B—modest, constant ADH secretion
- Type C—(“reset osmostat”)—downward resetting of the osmostat. Plasma sodium concentrations regulated at a lower level and continue to fall without therapy
- Type D—normal osmoregulation. ADH secretion varies appropriately with the plasma osmolality, but urine is concentrated even if ADH release is suppressed (e.g., vasopressin receptor is constitutively activated, production of antidiuretic compound other than ADH, postreceptor defect in transferring aquaporin-2 water channels).

Classification of SIADH etiology:

- CNS disorders (e.g., stroke, hemorrhage, infection, inflammation, trauma, neurosurgery, acute intermittent porphyria). Must differentiate SIADH from cerebral salt wasting (ADH secretion is secondary to reduced extracellular fluid volume)
- Ectopic (paraneoplastic) ADH production by tumors (small cell lung carcinoma in 75% of cases)
- Pulmonary diseases (pneumonia, asthma, atelectasis, pneumothorax)
- Drugs that mimic ADH, stimulate ADH release, potentiate ADH effects, or have unclear mechanisms (e.g., exogenous ADH analogs, SSRIs, phenothiazines, tricyclics, carbamazepine, cyclophosphamide, vincristine)
- Postoperative (likely mediated by pain afferents), transsphenoidal surgery
- Symptomatic HIV infection
- Hereditary/genetic—(e.g., gain-of-function mutation of arginine vasopressin receptor type 2—nephrogenic syndrome of inappropriate antidiuresis—causing constitutive receptor activation)
 - Aging
 - Unknown origin/idiopathic

Acute treatment includes water restriction and treating the underlying cause. In severe symptomatic cases associated with neurologic complications, hypertonic saline is administered to gradually correct hyponatremia. Loop diuretics can be useful by aiding water excretion. However, too rapid correction of serum sodium concentrations, especially in asymptomatic patients, can result in neurologic impairment from central pontine myelinolysis. Another complication of aggressive sodium correction is severe hypernatremia.

Pharmacologic treatment for SIADH includes vasopressin receptor antagonists (vaptans), which competitively bind to V-2 receptors. An advantage of these agents is their ability to reduce the need for severe fluid restriction, while correcting hyponatremia within a short time. During the initial 24 hours of administration, it is critical to prevent overly rapid correction of hyponatremia. Discontinuing vaptan therapy for more than 5 to 6 days requires monitoring for hyponatremic relapse. Therefore, it is prudent to taper the vaptan dose while restricting fluid intake. Side effects include thirst, polydipsia, and urinary frequency. Vaptans are ineffective in inappropriate antidiuresis caused by constitutive activating mutations of V-2 receptors.

Another treatment for SIADH is demeclocycline, a macrolide antibiotic, which induces nephrogenic diabetes insipidus by reducing adenylate cyclase expression, cAMP generation, AQP2 gene transcription, and AQP2 abundance in the renal medulla. Its frequent side effects include nausea and skin photosensitivity. In addition, oral urea is used to induce osmotic diuresis, which increases water excretion.

Cerebral (Renal) Salt-Wasting Syndrome (CSW): CSW is the extracellular volume depletion caused by abnormal sodium transport in patients with intracranial disease (and other conditions) and normal adrenal and thyroid function. CSW usually develops in the week following brain insult. Its duration is usually brief (2-4 weeks) but can last for several months. Both SIADH and CSW present with low serum

osmolality, elevated urine osmolality, and high urinary sodium concentrations. The basic difference is that in CSW, there is hypovolemia, while in SIADH, there is euvoolemia or mild hypervolemia. Urinary sodium concentrations are elevated in SIADH and CSW (>40 mEq/L). However, urinary sodium excretion (urinary sodium concentration [mEq/L] \times urinary volume [L/24 h]) is much higher than sodium intake in CSW but usually equals sodium intake in SIADH. Therefore, net sodium balance is negative in CSW. Failure to distinguish CSW from SIADH in hyponatremic brain-injured patients can lead to inappropriate therapy with fluid restriction.

In CRW, excessive sodium is lost in the proximal tubule, leading to reduced effective circulating volume. The two proposed mechanisms are the excessive secretion of natriuretic peptides (BNP and CNP) and the loss of renal sympathetic stimulation. Both the mechanisms reduce proximal and possibly distal sodium transport. The ensuing hypovolemia leads to baroreceptor activation increasing ADH secretion and water conservation in an attempt to return to a euvolemic state. In contrast, SIADH is due to an inappropriate euvolemic increase in ADH secretion. Depressed sympathetic drive and increased BNP concentrations are also associated with decreased renin and aldosterone concentrations, further inhibiting sodium retention.

The decreased serum sodium concentration associated with CRW reduces serum osmolality, and a tonicity gradient develops across the blood-brain barrier, causing or exacerbating cerebral edema. Symptoms include lethargy, agitation, headache, altered consciousness, seizures, and coma. Treatment involves correcting intravascular volume depletion and hyponatremia, plus replacing persistent urinary sodium loss with intravenous normal or hypertonic saline solutions. Saline infusion corrects the hypovolemia, removing a potent stimulus for ADH secretion, increasing free water excretion, and correcting the hyponatremia. There are reports of favorable responses to mineralocorticoid therapy. Once the patient is stabilized, enteral salt supplementation should be considered.

Hepatic Cirrhosis: Regardless of etiology (alcoholic, chronic hepatitis, autoimmune, genetic, cryptogenic), cirrhosis involves the loss of normal hepatic architecture and irreversible liver damage. Cirrhosis changes splanchnic circulation, causing mechanical obstruction to the portal flow and portal hypertension. Ascites occurs when portal pressures of >12 mm Hg cause intrahepatic sinusoidal hypertension. If portal pressure decreases to <12 mm Hg (e.g., after portosystemic shunt) ascites usually disappears. Presinusoidal portal hypertension (e.g., portal vein thrombosis) does not cause ascites in the absence of another predisposing factor.

In addition to the mechanical obstruction to portal flow, cirrhosis is associated with an increased portal venous inflow secondary to splanchnic arterial vasodilation and the opening of portosystemic collaterals. The latter, because of increased circulating vasodilators, such as nitric oxide and prostacyclin, reduces systemic vascular resistance and arterial pressure. Cardiac output increases in compensation. This hyperdynamic pattern can be found in cirrhotic patients even before ascites develops. In response to cirrhosis-associated vasodilation, endogenous vasoconstrictors and sodium-retaining neurohumoral mechanisms activate (RAAS, sympathetic nervous system, ADH) in an attempt to normalize perfusion pressure. The net effect is sodium and water retention. However, cirrhotics are effectively intravascularly volume depleted despite increased extracellular sodium stores, plasma volume, and cardiac output. As the disease progresses, solute-free water excretion is increasingly impaired because of the increased ADH secretion. Reduced water excretion plus ascites accumulation adds to total body fluid overload. The intravascular depletion leads to further “compensation,” including nonosmotic ADH secretion, worsening excess water retention, hypoosmolality, and dilutional hyponatremia. Nonosmotic ADH secretion is mediated via atrial, ventricular, aortic arch, and carotid sinus baroreceptors, which stimulate hypothalamic ADH release. This ADH secretion is paradoxical because serum osmolality is low. The net result is enhanced sodium and water retention, which attempts to correct the depleted circulatory volume. Sodium retention occurs despite increased total body

extracellular sodium concentrations. Hyponatremia severity correlates with worsening survival.

Other factors implicated in the development of hyponatremia and associated with cirrhosis include decreased renal PGE₂ production and slower ADH metabolism. Resistance to the natriuretic action of ANP may play a role in sodium retention. Renal perfusion in cirrhosis with ascites depends on a delicate equilibrium between the degree of stimulation of vasoconstrictor systems (sympathetic nervous system, RAAS) and the activity of intrarenal vasodilator compounds, (prostaglandins and nitric oxide). Imbalance between systemic vasoconstriction and local renal vasodilation can result in progressive renal failure (hepatorenal syndrome).

Stressed States: Exudation of protein-rich intravascular fluid from plasma to the extracellular space is the hallmark of stressed states (sepsis, pancreatitis, burns), resulting in relative intravascular hypovolemia. Such exudation leads to sequelae, including acute respiratory distress syndrome, diffuse edema, and abdominal compartment syndromes. Plasma ADH and aldosterone are usually increased during the initial phase of septic shock and burns and decrease later in the course. Extravascular fluid shifts diminish as the patient convalesces. The greater the fluid accumulation, the greater are morbidity and mortality. There is currently no direct treatment for this condition.

The endothelium tightly controls intravascular fluid exchange from the circulation to the tissues. Dysfunction of this barrier causes fluid exudation and edema. Various mechanisms appear involved in increasing membrane permeability. The main function of vascular endothelial (VE)-cadherin, a cell adhesion molecule localized to endothelial cell junctions, is regulating and forming a homophilic calcium-dependent bond with a twin on an adjacent cell. The cytoplasmic domain of VE-cadherin is bound to catenins, which attach to the cytoskeletal structure. When endothelial cells are exposed to permeability factors, they contract via myosin-actin crossbridge cycling, resulting in the dissociation of vascular endothelial cadherin from its adjacent homolog, forming interendothelial gaps. Permeability factors include proinflammatory cytokines (TNF, IL-6, IL-8, interferon- γ , IL-1 β), nuclear transcription factors (HMGB1, high-mobility group box1), transforming growth factor, and vascular endothelial growth factor (VEGF). These factors likely operate through the MyD88-ARNO-ARF6-signaling axis while also diminishing VE-cadherin expression.²⁶ VE-cadherin is internalized by VEGF-induced signaling through VEGF receptors and undergoes tyrosine phosphorylation leading to greater vascular endothelial cell detachment and transendothelial permeability. Matrix metalloproteases (e.g., MMP-9, gelatinase b) have been implicated as degrading interendothelial adherens junction proteins. An associated mechanism is activation of Rho-A GTPase, which increases actomyosin contractility, inducing intercellular junction breakdown and enhancing permeability.²⁷

Hypovolemic Disorders

Diabetes Insipidus (DI): DI, polyuria (defined as a urine output exceeding 3 L/day in adults and 2 L/m² in children) caused by plasma ADH deficiency or renal resistance to ADH's effects, is characterized by the failure to appropriately concentrate urine.

In the absence of ADH (<0.5 pg/mL), renal collecting duct membranes become impermeable to water (fewer aquaporin-2 water channels), thereby allowing the formation of dilute filtrate in proximal nephrons. This results in the excretion of relatively large urine volumes of low osmolality (≤ 100 mOsm/kg), causing hypovolemia and even hypotension. These stimulate hypothalamic osmoregulators, encouraging water intake via thirst. With normal thirst and access to water, fluid intake increases to compensate for most of the water loss. Consequently, even in the complete absence of vasopressin, urine output and fluid intake increase in parallel, maintaining plasma osmolality within the normal range. Severe dehydration and hypernatremia occur when access to water or intravenous fluids is lacking or there is coexisting thirst deficiency.

The most common cause of DI is inadequate neurohypophyseal ADH secretion, resulting in partial or complete central DI. Nephrogenic DI is characterized by normal ADH secretion with varying degrees of renal resistance to its antidiuretic effect. Another mechanism is the suppression of ADH secretion by excessive water intake, as seen in primary polydipsia. ADH insufficiency can rarely result from increased metabolic clearance during pregnancy because of the placental production of the aminopeptidase vasopressinase, which rapidly degrades ADH, causing a four- to six-fold increase in ADH metabolism. In most women, the pituitary compensates by producing more ADH. In some women, presumably those with diminished ADH secretory reserves, polyuria develops. This usually occurs during the third trimester and spontaneously resolves after placental delivery.

Central DI can be caused by defects along the ADH neurosecretory pathway, including genetic mutations affecting ADH synthesis and packaging; damage to ADH-producing magnocellular neurons or the supraopticohypophyseal tract; and disorders of neurohypophyseal hormone release. Five percent of central DI cases are familial/genetic; >50 mutations have been identified in the AVP-neurophysin II gene (chromosome 20) and other loci have been described. Furthermore, 0% to 50% of cases are considered "idiopathic" (autoimmune, aberrant posterior pituitary blood supply). Other causes include neoplasms involving the hypothalamus (craniopharyngiomas, germinomas, metastatic disease of the posterior pituitary [breast or lung cancer]) and granulomas (sarcoidosis, tuberculosis, Wegener's granulomatosis, Langerhans cell histiocytosis [histiocytosis X]). In the ICU, common causes are trauma—for example, closed head injury, postcraniotomy, anterior communicating artery (ACA) aneurysmal rupture causing subarachnoid or intracerebral hemorrhage (ACA aneurysms and their treatment can compromise hypothalamic blood supply), brain abscess, subdural hemorrhage (DI persisted for 3 months in 8% of survivors), and ischemic brain injury. Transient or permanent DI occurs in 8% to 9% of endoscopic transsphenoidal surgeries.

Nephrogenic DI may reflect an intrinsic renal defect or may be acquired secondary to metabolic disease or medication. It is characterized by complete or partial deficiency to the renal antidiuretic response to normal or increased ADH concentrations. Adults generally have an acquired form. Normal aging can also result in partial nephrogenic DI. Drugs inducing nephrogenic DI; lithium is the most common offender, with nephrogenic DI reported in 25% to 55% of patients receiving lithium. With long-term use, lithium-induced DI can become irreversible. Hypercalcemia and hypokalemia can partially block renal ADH action. Hereditary forms of nephrogenic DI are due to defective renal ADH V2 receptor (males with X-linked recessive defect in chromosome region Xq28) or aquaporin-2 genes.

Adipsic DI is a condition where impaired thirst complicates deranged water balance. It is closely associated with ACA aneurysm clipping and is characterized by dramatic increases in plasma ADH concentrations during nonosmotic stimuli such as hypotension. This situation reflects intact supraoptic and paraventricular nuclei and posterior pituitary with abnormalities of the anterior pituitary osmoreceptors. Vascular supply to this latter area is from small arterioles supplied by the anterior communicating artery. Disrupting this blood supply causes infarction that impairs ADH secretion response to thirst or hyperosmolality.

Diagnosis of DI is made when urine volume is markedly increased and urine osmolality is very low (<100 mmol/kg), associated with elevated plasma osmolality (>300 mmol/kg) and serum sodium concentrations (>145 mmol/L). However, other causes of polyuria must be excluded—for example, excessive fluid resuscitation, osmotic diuresis, hypertonic saline infusion, and "triple H therapy" (hypervolemia, hemodilution, and hypertension), which are used to treat cerebral vasospasm. When basal plasma osmolality and sodium are within normal ranges, osmotic stimulation with a formal water deprivation test or hypertonic saline infusion (if necessary) to achieve plasma osmolality of >295 to 300 mOsm/kg is indicated. If there is no change in the water loss despite fluid deprivation, the type (central or nephrogenic) of DI should be determined by monitoring the response to

administered ADH or 1-deamino-8-D-arginine vasopressin (DDAVP-desmopressin), a synthetic ADH analog. A significant increase in urine osmolality 1 to 2 hours after subcutaneously or intravenously injecting 1 μ g of DDAVP indicates insufficient endogenous ADH and probable central DI. Little or no increase in urinary concentration indicates renal resistance to ADH and severe nephrogenic DI. Some cases are not as straightforward and require further evaluation with a 2-day therapeutic trial of DDAVP, an MRI of the hypothalamus plus pituitary, and plasma ADH and copeptin measurements.

While diagnosing and identifying the cause of the DI, it is imperative that adequate fluid intake is maintained. The treatment for central DI is either intravenous ADH (vasopressin) or oral, intranasal, or parenteral DDAVP. DDAVP is a synthetic ADH analog with a longer half-life than the native hormone. In nephrogenic DI, therapeutic options are only partially effective: low-sodium diet, thiazide diuretics, prostaglandin E synthetase inhibitors, and nonsteroidal antiinflammatory drugs may partially decrease urine volume. The potassium-sparing diuretic amiloride is used in lithium-induced nephrogenic DI (it induces natriuresis and reduces lithium uptake in the distal tubules and collecting ducts, blunting lithium's inhibition of water reabsorption). Pregnancy-associated DI can be controlled with vasopressinase-resistant DDAVP but not ADH.

Osmotic Diuresis: Osmotic diuresis is characterized by increased urination caused by nonreabsorbed solutes (e.g., glucose and urea) in renal proximal tubules. Increased osmotic pressure within the tubule causes luminal water retention, reducing water reabsorption and increasing urine output. When blood glucose exceeds 160 to 180 mg/dL, the proximal tubule is overwhelmed, causing glycosuria. Osmotic urea diuresis is common in the ICU, associated with enteral nutrition and resolving acute renal failure. The electrolyte-free water loss may cause hypernatremia.

Therapeutic agents (e.g., mannitol) are used to increase urine output and decrease extracellular fluid volume. Mannitol, freely filtered by the glomerulus and not reabsorbed, acts as an osmotic diuretic, increasing urinary losses of electrolyte-free water. Osmotic substances increase blood osmolality, thereby pulling water from the interstitial space and increasing GFR and urine output. Failure to replace fluid losses can lead to volume depletion and hypernatremia. However, if very high doses of hypertonic mannitol are infused, or if it is administered to patients with preexisting renal failure, mannitol is retained in the circulation. The resulting plasma osmolality increase, like that produced by hyperglycemia, causes osmotic movement of water out of cells, leading to extracellular fluid volume expansion and dilutional hyponatremia. This can result in intravascular fluid overload, especially if the excess fluid and osmotic substances cannot be excreted.

Osmotic diuresis generally leads to significant free water losses and can cause or contribute to hypernatremia. However, with glycosuria secondary to uncontrolled diabetes mellitus, diabetic ketoacidosis, and hyperosmolar hyperglycemic state, most patients are mildly hyponatremic. The serum sodium concentration reflects the balance between the dilutional effect of water moving out of cells in response to the hyperglycemia-induced increase in serum osmolality (dilutional hyponatremia—i.e., true hypertonic hypervolemic hyponatremia) and the increased water excretion due to glycosuria-induced osmotic diuresis.

Treating water losses secondary to osmotic diuresis involves reducing the nonreabsorbed solute either by stopping its administration (e.g., mannitol) or treating the underlying pathologic condition (e.g., reduce blood glucose concentrations). Furthermore, excessive dehydration should be prevented by administering sufficient fluids.

Cold Diuresis: Cold or cold-induced diuresis occurs during exposure to a hypothermic environment and during mild to moderate accidental and therapeutic hypothermia. During therapeutic hypothermia, cold diuresis is most apparent during the induction phase. Cold diuresis is characterized by increased sodium and chloride excretion leading to enhanced water loss, decreased blood volume, and increased blood viscosity. The latter augments the increased viscosity secondary to the hypothermia. Vasoconstriction and hypovolemia caused by

hypothermia are most problematic; thus, vasodilation during rewarming must be countered by fluid resuscitation to avoid hypotension.

Possible causes of cold diuresis include the redirection of blood from vasoconstricted extremities to the core, leading to increased core fluid volume. The latter leads to increased renal blood flow and diuresis. ADH appears to be involved in cold diuresis. Some investigators report decreased ADH, while others report that although ADH concentrations are elevated, cold exposure inhibits renal V_2 receptors, decreasing V_2 receptor mRNA expression and inducible renal medullar AQP-2 water channel protein expression.²⁸ ANP does not appear to be involved in cold diuresis.

Heat and Exercise-Induced Disorders: Sweat is hypoosmotic relative to plasma; hence, excessive sweating can lead to significant water loss, reaching >2.5 L/h during strenuous exercise.²⁹ Sweat sodium concentrations range from 15 to 90 mmol/L, with an average of 40 mmol/L. As sweating increases, sodium secretion rates proportionally increase. However, heat acclimatization lowers sodium chloride concentration. Maintaining normal hydration during exercise maintains cardiovascular and thermoregulatory responses. Whenever possible, oral, rather than IV, rehydration should be performed. Although IV fluids rehydrate faster, the benefits are often transient, with the major limitation being the bypassing of the oropharynx. Oropharyngeal stimulation influences thirst sensation, ADH release, cutaneous vasodilation, and mean arterial pressure.³⁰ Therefore, drinking water plus electrolyte solutions to minimize dehydration is necessary during and following significant exercise and heat exposure. To maintain adequate hydration elite athletes ingest ~200 to 800 mL/h. Less acclimatized participants should not drink as much as possible but according to the stimulation of thirst and no more than 400 to 800 mL/h.

In collapsed marathon runners, there is a significant incidence of hypernatremia with hyperosmolality and hyponatremia with hypoosmolality. The latter is often due to hyperhydration, caused by considerable water ingestion. Hyponatremia, hyperthermia, hypertonic hypernatremia, orthostatic hypotension due to decreased peripheral resistance, and dehydration can each contribute to cerebral dysfunction.^{31,32} Moreover, it is crucial to differentiate between hypernatremia and hyponatremia since the immediate management differs. Administering hypotonic fluids to severely hyponatremic patients may cause fatal cerebral edema, evidenced by seizures and/or coma. Therefore, laboratory testing to determine serum sodium concentration is vital to direct therapy.

Heat stress illness (HSI), also called *heat-related illness*, includes benign rash, heat syncope, heat cramps, heat exhaustion (most common HSI), and heat stroke (most severe form). During 2001–2010, ~28,000 HSI hospitalizations occurred in 20 states.³³ HSI occurs during heat exposure with and without exercise. Obesity, heart failure, pre-existing neuropsychiatric disorder, psychotropic drugs intake (e.g., phenothiazines, cocaine), and strenuous outdoor work³⁴ are associated with increased HSI risk. HSI development and severity are significantly related to hydration status and ability to sweat.^{35,36} HSI is exacerbated by hypovolemia and plasma hyperosmolality, which inhibit thermoregulatory responses, such as cutaneous vasodilation and sweating.³⁷ Elevated core temperature does not stimulate ADH secretion except with increased serum osmolality.³⁸ HSI treatment includes rapid cooling, fluid replacement, and physiologic support.

CONCLUSION

Maintaining homeostatic water balance is a vital body function commonly disordered in critically ill patients due to combinations of their acute illness, underlying chronic diseases, treatments, and aging. Modern critical care medicine needs to better understand water metabolism, especially the microcirculatory consequences of edematous and overhydrated states. Such a better understanding should influence treatment—for example, whether to treat with saluretic diuretics that enhance sodium excretion or with aquaretics that increase water excretion.³⁹

KEY POINTS

1. Water, the liquid of life for all organisms, has many functions: carrier of essential substances; body coolant, lubricant, reactant and product in metabolic reactions; and shock absorber.
2. Water homeostasis is controlled by thirst, the ability to find and ingest water, kidney function, sweating, and endogenous systems.
3. Endogenous systems active in water metabolism include ADH, renin-angiotensin-aldosterone system, natriuretic peptides, dopamine, and renal intracrine mechanisms.
4. Environmental conditions—extreme heat and cold—can cause disordered water homeostasis, as can diarrhea, drugs, excessive water ingestion and disorders of endogenous systems (diabetes insipidus, SIADH).
5. In stressed states (e.g., sepsis, burns, and trauma), plasma ADH and aldosterone are increased during the initial phase accompanied by extravascular exudation of protein-rich fluids.
6. Critically ill patients are totally dependent on their care providers for maintaining water homeostasis and for preventing and correcting disordered homeostasis.

SERUM CALCIUM CONCENTRATION

Calcium is essential to many physiologic phenomena, including the preservation of the integrity of cellular membranes, neuromuscular activity, regulation of endocrine and exocrine secretory activities, blood coagulation, activation of the complement system, and bone metabolism. The normal range for total serum calcium must be established for each laboratory, and it varies according to the method used. Total serum calcium concentration is a combination of protein-bound calcium, ionized calcium, and nonionized calcium.¹

Protein-Bound Calcium

Approximately 40% of total calcium is bound to serum proteins, and 80% to 90% of this calcium is bound to albumin. Variations in serum protein proportionately alter the concentration of the protein-bound and total serum calcium. An increase in serum albumin concentration of 1 g/dL increases protein-bound calcium by 0.8 mg/dL, whereas an increase of 1 g/dL of globulin increases protein-bound calcium by 0.16 mg/dL. However, the validity of this correction in critical illness has been questioned, with multiple authors emphasizing the importance of directly measuring serum ionized calcium concentrations in this patient population.^{2,3} Marked changes in serum sodium concentration also affect the protein binding of calcium. Hyponatremia increases, whereas hypernatremia decreases, protein-bound calcium. Changes in pH also affect protein-bound calcium, and an increase or decrease of 0.1 pH, respectively, increases or decreases protein-bound calcium by 0.12 mg/dL.

Free (Ionized) Calcium

Ionized calcium is the biologically active form of calcium responsible for most physiologic actions of calcium in the body. The serum ionized calcium concentration in normal subjects ranges from 4.0 to 4.9 mg/dL, or 47% of the total serum calcium. Acidosis decreases protein binding, thereby increasing the ionized fraction of calcium. An increase in serum pH of 0.1 unit causes a decrease in ionized calcium of 0.16 mg/dL.

Nonionized Calcium

The nonionized form of calcium is also called *complexed calcium*. Calcium complexes are formed with bicarbonate, phosphate, and acetate and constitute approximately 13% of the total serum calcium. Complexed calcium has been found to be increased twofold in patients with uremia.

Cytosolic Free Calcium

The normal concentration of cytosolic calcium is about 100 nM/L, which is 10,000-fold lower than the concentration of extracellular calcium. This very steep gradient is maintained by an energy-driven calcium pump, known as the *plasma membrane Ca⁺⁺-ATPase*. In certain types of cells, a Na⁺/Ca⁺⁺ exchanger, energized by the Na⁺ gradient, helps drive cytosolic calcium into the extracellular space. Part of the cellular calcium is sequestered in intracellular organelles, including

the endoplasmic reticulum, the sarcoplasmic reticulum in muscle cells, and the mitochondria. These organelles are endowed with their own calcium pumps that help preserve the very low levels of free cytosolic calcium. Calcium-dependent intracellular signaling generally requires a 10-fold increase in free cytosolic calcium. Elevation in cytosolic calcium is mediated by the activation of calcium channels, which allows passive calcium flux down electrochemical gradients.⁴
